## ABSTRACT

CO observations in active galactic nuclei and star-bursts reveal high kinetic temperatures. Those environments are thought to be very turbulent due to dynamic phenomena such as outflows and high supernova rates.

We investigate the effect of mechanical heating on atomic fine-structure and molecular lines, and their ratios. We try to use those ratios as a diagnostic to constrain the amount of mechanical heating in an object and also study its significance on estimating the H<sub>2</sub> mass. Equilibrium photo-dissociation models (PDRs hereafter) were used to compute the thermal and chemical balance for the clouds. The equilibria were solved for numerically using the optimized version of the Leiden PDR-XDR code. Large velocity gradient calculations were done as post-processing on the output of the PDR models using RADEX.

High-*J* CO line ratios are very sensitive to mechanical heating ( $\Gamma_{\text{mech}}$  hereafter). Emission becomes at least one order of magnitude brighter in clouds with  $n \sim 10^5 \text{ cm}^{-3}$  and a star formation rate of  $1 M_{\odot} \text{ yr}^{-1}$  (corresponding to  $\Gamma_{\text{mech}} = 2 \times 10^{-19} \text{ erg cm}^{-3} \text{ s}^{-1}$ ). Emission of low-*J* CO lines is not as sensitive to  $\Gamma_{\text{mech}}$ , but they do become brighter in response to  $\Gamma_{\text{mech}}$ . Generally, for all of the lines we considered,  $\Gamma_{\text{mech}}$  increases excitation temperatures and decreases the optical depth at the line centre. Hence line ratios are also effected, strongly in some cases. Ratios involving HCN are a good diagnostic for  $\Gamma_{\text{mech}}$ , where the HCN(1-0)/CO(1-0) increases from 0.06 to 0.25 and the HCN(1-0)/HCO<sup>+</sup>(1-0) increase from 0.15 to 0.5 for amounts of  $\Gamma_{\text{mech}}$  equivalent to 5% of the surface heating rate. Both ratios increase to more than 1 for higher  $\Gamma_{\text{mech}}$ , as opposed to being much less than unity in pure PDRs.

The first major conclusion is that low-*J* to high-*J* intensity ratios will yield a good estimate of the mechanical heating rate (as opposed to only low-*J* ratios). The second one is that the mechanical heating rate should be taken into account when determining  $A_V$  or equivalently  $N_H$ , and consequently the cloud mass. Ignoring  $\Gamma_{\text{mech}}$  will also lead to large errors in density and radiation field estimates.

## 1. Introduction

The study of molecular gas in external galaxies dates back to the mid-seventies, with the detection of ground-state emission from CO (the most abundant molecules after hydrogen) in a small number of bright nearby galaxies. At present observations CO and many other molecules exist for a very large number of galaxies, near and far. It is important to be able to interpret the emission in the various lines from those galaxies, since that gives us insight in the physics dominating the interstellar medium in the star forming regions of these extra-galactic sources.

For decades, line observations had to be done from the ground in a frequency range limited by atmospheric opacity, so that for most molecular species only the low transitions were accessible. Level transitions at higher rest frame frequencies, were only possible for distant galaxies for which the high-frequency lines were red-shifted into atmospheric windows accessible from the ground. In the past few years the *Herschel* Space Observatory (Pilbratt et al. 2010) operating outside the Earth's atmosphere has provided direct observations of spectral lines at frequencies hitherto impossible or hard to access.

By way of example we mention the determination of extensive <sup>12</sup>CO rotational transitions ladder in galaxies such as M82 (Loenen et al. 2010; Panuzzo et al. 2010; Kamenetzky et al. 2012) and Mrk231 (van der Werf et al. 2010;

González-Alfonso et al. 2012). *Herschel* ran out of coolant in April 2013, but at about the same time, the Atacama Large Millimeter Array (ALMA) became operational. With ALMA, a large fraction of the important submillimeter spectrum is still accessible, at vastly superior resolution and sensitivity, allowing detection and measurement of diagnostic molecular line transitions largely out of reach until then.

Conducting detailed studies of the physical properties of the molecular gas of close-by star-forming galaxies involves a challenging inversion problem, where resultant line intensities are used to constrain gas densities, molecular content, kinetic temperatures and the nature and strengths of the radiation field exciting the gas. In order to solve this problem, it is necessary to get a clearer understanding of the underlying physics and phenomena characterizing specific regions such as galaxy centres, including our own.

A good starting point to analyse molecular gas emission is the application of the so-called large-velocity-gradient (LVG) models (Sobolev 1960). This assumes an escape probability formalism for photons in different geometries which simplifies solving for the radiative transfer significantly. LVG models have been widely used by the ISM community with some other basic assumptions to estimate the molecular density of the gas, species abundances and the kinetic temperature (Henkel et al. 1983; Jansen et al. 1994; Hogerheijde & van der Tak 2000;

Schöier *et al.* 2005; Krumholz 2013, among others). These models provide only an insight for the physical and chemical properties of the clouds; the actual nature of the source of energy cannot be determined using those LVG models, see for example Israel (2009a,b). The next level of sophistication over LVG modelling involves the application of photon-dominated region (PDR) models (Ferland *et al.* 1998; Hollenbach & Tielens 1999; Le Petit *et al.* 2006; Röllig *et al.* 2007; Bisbas *et al.* 2012). These models self-consistently solve for the thermal and chemical structure of clouds irradiated by UV photons.

In PDRs, energy sources other than UV photons could dominate the thermal and chemical balance. In the vicinity of an active galactic nucleus (AGN), PDR models can be augmented by models for X-ray dominated region (XDRs Maloney *et al.* 1996; Bradford *et al.* 2003; Meijerink & Spaans 2005; Papadopoulos *et al.* 2011; Bayet *et al.* 2011; Meijerink *et al.* 2011).

In both these models, the underlying assumption is that the thermal balance is dominated by radiation. The physical situation in galaxy centres, star-bursts and dense cores (Pineda *et al.* 2010) is, however, more complicated. There are other processes, such as mechanical feedback that may also excite the gas mechanically (Loenen *et al.* 2008; Ossenkopf & Mac Low 2002; Ossenkopf 2002; Kazandjian *et al.* 2012).

Although these models are much more sophisticated than LVG models, a simplified comparison of many PDR codes<sup>1</sup> (Röllig *et al.* 2007) has shown that they shed a statistical view on the underlying processes. This is particularly true in the transition zone from atomic to molecular gas, where an order of magnitude difference between the various quantities compared in the models is not uncommon. Such discrepancies are mainly due to the uncertainties in the chemical reaction constants, which in turn influence the reaction rates, abundances and thermal balance (Vasyunin *et al.* 2004). In addition to those uncertainties observations of extra-galactic sources have spatial resolution limitations. For example the resolution of *Herschel* for the nucleus of NGC 253 is on the order of 1 kpc. The surface area covered by such a beam size contains a large number of clouds. In modelling the nucleus of such galaxies one might need to consider two or more PDRs simultaneously. Although considering more than one PDR component improves the fits significantly, the increased number of free parameters usually has a negative impact on the statistical significance of those fits. This is particularly valid whenever the number of lines being fitted is low.

Here we follow the modelling of paper I (Kazandjian *et al.* 2012) where we studied the effect of mechanical heating ( $\Gamma_{\text{mech}}$ ) by considering its impact on the thermal and chemical structure (abundances, column densities and column density ratios of species) of PDRs. Hence our basic modelling premise will be the same in this paper. Namely, an 1D semi-infinite plane-parallel geometry is adopted. It is assumed that the slab is illuminated with a FUV source from one side. Another major assumption is that the clouds are in an equilibrium state. Since equilibrium is assumed, we consider a simplified recipe in accounting for mechanical feedback. For simplicity the contribution of mechanical heating to the total heating budget, is added in an ad-hoc fashion uniformly throughout the cloud.

Our approximation of the effect of mechanical heating by a single homogeneous heating term is a simplification. In practice, the mechanical energy which could be liberated by super-

nova events or gas outflows, is deposited locally in shock fronts. In these fronts, which are the interaction surfaces between high speed flows and the ambient medium, the energy is not necessarily distributed uniformly throughout the cloud volume. On the other hand, this energy will eventually cascade to smaller spatial scales and thermalize en route to equilibrium. The efficiency of the “thermalization” is conservatively taken to be 10%. Consequently the approximation we adopt may be less applicable to systems where the dynamical time-scales are comparable to the thermal and chemical time-scales; this occurs for example in clouds in the inner kpc of galaxy centres. Our choice for the ranges in mechanical heating explored is based primarily on estimates by Loenen *et al.* (2008). They found that fits for the line ratios of the first rotational transition ( $J = 1-0$ ) of the molecules HCN, HNC and HCO<sup>+</sup> are greatly enhanced by using PDR models which included “additional” heating. They attributed this extra heating to dissipated turbulence and provided an estimates for it. The major conclusion of Paper I was that even small amounts of mechanical heating, as low as 1% of the surface UV heating, has significant effects on the molecular abundances and column densities. Those effects are mainly manifested as enhanced CO abundances which could increase by up to a factor of two. Although this might not seem a significant effect, the column densities of the high density tracers such as HCN and HNC increase (or decrease) by an order of magnitude depending on the amount of  $\Gamma_{\text{mech}}$ .

The aim of this paper is to understand both the ground-state and the more highly excited states of molecular gas in galaxy centres and to determine whether turbulence or shocks can make a major contribution to the molecular emission. In other words, we thus extend the work done in Paper I, which focused on the chemical abundances and column densities only, by studying the signature of mechanical feedback on selected atomic and molecular emission lines.

The models presented in this paper also apply to other regions where the gas is, e.g., (1) heated by young stellar objects (YSO’s), (2) stirred up turbulently by the fast motions of stars, or (3) violently heated by supernovae. Since we assume equilibrium, applying our models to those regions is of course an approximation. In all cases, non-negligible amounts of mechanical energy may be eventually injected into the ISM (Leitherer *et al.* 1999). Part of this energy is then converted to mechanical heating, particularly important in so-called star-burst galaxies.

Since the amount of turbulent energy absorbed by the ISM is a priori unknown, we explore a wide range of possibilities of turbulent heating contributions to PDRs. In our approach, the additional heating self-consistently modifies the emission. In this paper we provide two new estimates of mechanical heating rates and re-enforce our assumptions of Paper I (see the methods section below).

Although we introduce an extra free parameter (the amount of absorbed turbulent energy), the basic molecular abundances and gas parameters are self-consistently determined by the equilibria that we solve for in the PDR models. In the following we explore, using those 1D equilibrium PDR models, the effect of mechanical heating ( $\Gamma_{\text{mech}}$ ) on atomic and molecular line intensities for a range of : densities, FUV flux ( $G_0$ ), metallicities and column densities. In doing so we aim to find good diagnostics for  $\Gamma_{\text{mech}}$  and to check for the usefulness of such PDR models with an additional “ad-hoc” heating term in constraining mechanical heating.

<sup>1</sup> In the comparison benchmark the chemistry involved 4 elements (H, He, O and C) and 30 species. For more details on the benchmarks and the codes used see <http://goo.gl/7Hf6mD>

## 2. Methods

A PDR is primarily characterized by its gas number density, the FUV flux of the environment and its spatial extent (usually measured in  $A_V$  or alternatively the column density of H). The conversion of  $A_V$  to  $N_H$  is given by  $N_H = 1.87 \cdot 10^{21} A_V (Z_\odot/Z) \text{ cm}^{-2}$ . In PDRs, the main heating sources are typically the FUV photons irradiating the cloud surface. In addition to FUV heating, cosmic-rays penetrating the molecular interior of clouds also contribute to heating the gas. To this, we now apply increased amounts of (mechanical) heating which might be due to absorbed turbulent energy. We discuss in section-2.1 the details of the inclusion of mechanical heating into the PDR models.

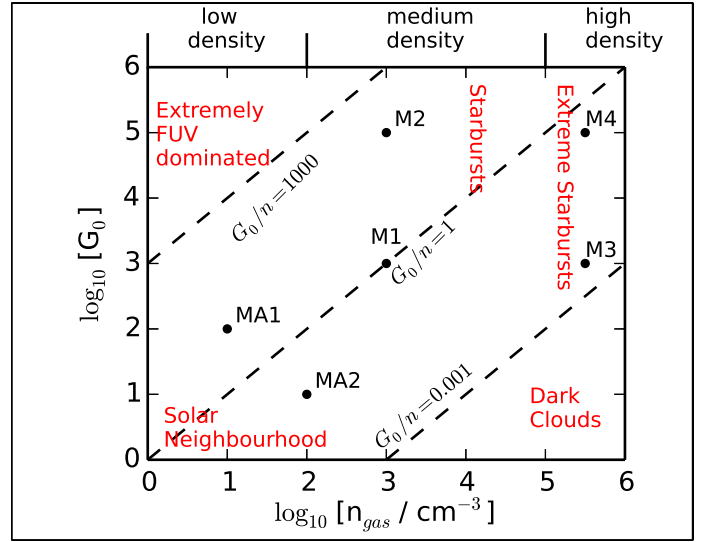

In modelling a PDR, we used an optimized version of the PDR code described by Meijerink & Spaans (2005); Meijerink *et. al.* (2007). For a detailed description of the code used, we refer the reader to the methods section of Paper I and to Meijerink & Spaans (2005). The ISM is modelled as a homogeneous cloud of uniform gas density illuminated by a UV source from the side. For simplicity, the cloud is assumed to be an equilibrium plane-parallel semi-infinite slab. The thermal state and the chemical abundances of all the species within the cloud are solved for self-consistently. For more details see 2.2. We explore a parameter space similar to that in Paper I where  $1 < n < 10^6 \text{ cm}^{-3}$  and  $1 < G_0 < 10^6$ . In Fig-1 we show a schematic diagram (a template grid) for the  $(n, G_0)$  parameter space where we highlight some situations in which the ISM could be. We divide the grid into three grades in density: low ( $0 < n < 10^2 \text{ cm}^{-3}$ ), medium ( $10^2 < n < 10^5 \text{ cm}^{-3}$ ) and high ( $10^5 < n < 10^6 \text{ cm}^{-3}$ ). In addition to those two fundamental parameters specifically for a PDR, we study the response of a cloud's emission on increasing amounts of  $\Gamma_{\text{mech}}$  for different depths  $A_V$ . We specifically consider emission in atomic fine-structure lines of [OI], [CII], and [CI] in addition to the various molecular line transitions of CO,  $^{13}\text{CO}$ , HCN, HNC, HCO<sup>+</sup>, CN, and CS.

A full range of possible ‘‘extra’’ heating rates is explored. From pure PDRs where heating is dominated by the FUV source, to regions where the heating budget is dominated by turbulence. This allows us not just to constrain the effect of turbulent heating (as we will demonstrate throughout the paper), but also to improve on estimates of molecular cloud column densities in cases where turbulent heating contributions are ignored.

A difference with respect to the approach in Paper I lies in the choice of the  $\Gamma_{\text{mech}}$  parametrization. Based on the conclusions of Paper I, we decided that in a scheme for probing the effects of  $\Gamma_{\text{mech}}$  on a grid of PDR models, it is more convenient to include it in the heating budget as a per unit mass term, rather than a per unit volume one (see next section).

In this paper, we consider higher H column densities than included in Paper I, expanding coverage from columns corresponding to  $A_V = 10$  mag to columns corresponding to  $A_V = 30$  mag. The main constraint on this depth is the limit in the interpolation tables used in the PDR code for computing the self-shielding of CO. In general, the properties deep inside the molecular cloud ( $A_V > 10$  mag) are constant. This fact can be exploited to approximate the cloud properties at even higher  $A_V$  values.

We note that all figures shown in main text of this paper correspond to PDRs of solar metallicity. We have, in fact, also considered other metallicities, including those as low as  $Z = 0.1Z_\odot$  which characterize the most metal-poor dwarf galaxies as well as  $Z = 2Z_\odot$  typical to galaxy centres. At any fixed  $A_V$ , the corresponding H column density ( $N_H = N(\text{H}) + 2N(\text{H}_2)$ )

**Fig. 1.** Diagram indicating different regimes in the  $(n, G_0)$  parameter space. The labelled points correspond to our reference models used throughout the paper (see Table-2).

is taken to depend inversely on the cloud metallicity in a linear fashion. We illustrate this as follows. PDRs with the lowest metallicity and highest  $A_V = 30$  mag considered will have  $N_H = 5.6 \times 10^{23} \text{ cm}^{-2}$  compared to  $N_H = 9.4 \times 10^{21} \text{ cm}^{-2}$  for clouds with a  $Z = 2Z_\odot$  and an  $A_V = 10$  mag. Figures corresponding to non-solar metallicity conditions can be found in the Appendix.

### 2.1. Mechanical heating

A major conclusion of Paper I was that mechanical heating must not be neglected in calculating heating-cooling balances. Addition of a modest amount of mechanical heating to the cloud volume, corresponding to no more than a small fraction of the UV surface heating, already suffices to alter the chemistry of the PDR significantly.

The PDR model grids in Paper I were parametrized by  $n$  (first axis - horizontal axis),  $G_0$  (second axis - vertical axis) and  $\Gamma_{\text{mech}}$  (per unit volume, third axis). The parameter space was sampled by picking equidistant points in log space for each axis. The disadvantage of such a representation is that for all the models each grid (as a function of  $n$  and  $G_0$ ) has the same amount of  $\Gamma_{\text{mech}}$  independent of  $n$ . For example, a cloud with  $n = 1 \text{ cm}^{-3}$  would have the same amount of  $\Gamma_{\text{mech}}$  added as one with  $n = 10^6 \text{ cm}^{-3}$ . What might be a huge amount for the former cloud would be negligible for the latter. It is thus preferable to parametrize  $\Gamma_{\text{mech}}$  adaptively for each density level. In the following, the third axis is replaced by the new parametrization of  $\Gamma_{\text{mech}}$ . This new parametrization is defined using the symbol  $\alpha$  where :

$$\alpha = \frac{\Gamma_{\text{mech}}}{\Gamma_{\text{surf}}} \sim \frac{\Gamma_{\text{mech}}}{\Gamma_{\text{photo}}} \quad (1)$$

where  $\Gamma_{\text{surf}}$  is the total heating rate at the surface of the PDR (at  $A_V = 0$  mag), and  $\Gamma_{\text{photo}}$  is the photo-electric heating rate. The expression relating it to  $n$  and  $G_0$  is  $\Gamma_{\text{photo}} = \epsilon_0 G_0 n$ , where  $\epsilon$  is the heating efficiency. The treatment of mechanical heating in terms of the total surface heating is to a high degree of accuracy equivalent to a parametrization as a function of  $\Gamma_{\text{photo}}$ .  $\Gamma_{\text{photo}}$  is linearly proportional to  $n$ . For a certain section in  $\alpha$  (in the third

axis) each model thus has a  $\Gamma_{\text{mech}}$  proportional to its density. We note that this new parametrization is also equivalent to saying that  $\Gamma_{\text{mech}}$  is added per unit mass, since multiplying  $n$  by  $m_H$  (the mass of a hydrogen atom) corresponds to a mass density.

To make this clear, we will now consider an example. The case  $\alpha = 0$  corresponds to a situation where no mechanical heating is present in the PDR (what we call this a reference or pure PDR model). On the other hand, the case  $\alpha = 1$  represents a model where the amount of mechanical heating added to the reference model, is equivalent to the heating at its surface. We now point the reader to the right panel of Figure-2, which is a grid of reference models (i.e a section in  $\alpha = 0$ ). For example, the surface heating for a model with  $n = 10^4 \text{ cm}^{-3}$  and  $G_0 = 10^3$  is  $\sim 10^{-19} \text{ erg cm}^{-3} \text{ s}^{-1}$ . In a grid with  $\alpha = 0.01$ , this model would have an amount  $\Gamma_{\text{mech}} = 0.01 \times 10^{-19} = 10^{-21} \text{ erg cm}^{-3} \text{ s}^{-1}$  added to its heating budget. More such examples are summarized in Table-1.

**Fig. 2.** (Left) Mechanical heating rates applied to the SPH simulation of a dwarf galaxy (Pelupessy 2005; Pelupessy & Papadopoulos 2009). The maximum heating rate is  $\sim 10^{-22} \text{ erg cm}^{-3} \text{ s}^{-1}$ . (Right) Surface heating ( $\Gamma_{\text{surf}}$ ) for zero mechanical heating ( $\alpha = 0$ ) for  $Z = Z_{\odot}$ . The heating rates range from  $\sim 10^{-22}$  to  $\sim 10^{-20} \text{ erg cm}^{-3} \text{ s}^{-1}$  at  $n \sim 10^3 \text{ cm}^{-3}$ . An SPH particle with  $n \sim 10^3 \text{ cm}^{-3}$  and a maximum  $\Gamma_{\text{mech}}$  (in the simulation) would have an  $\alpha = 1$  and 0.1 if its  $G_0$  is 1 and  $10^3$  respectively. The black points in the right panel correspond to the the boundary points in  $n$  and  $\Gamma_{\text{mech}}$  distribution (plotted as open circles in the left panel) .

$n$ ( $\text{cm}^{-3}$ )	$G_0$	$\Gamma_{\text{mech}}$ ( $\text{erg cm}^{-3} \text{ s}^{-1}$ )	$\alpha$	SFR density ( $M_{\odot} \text{ yr}^{-1} \text{ kpc}^{-3}$ )
$10^2$	1.0	$3.5 \times 10^{-27}$	$1 \times 10^{-4}$	$< 0.01$
$10^4$	$10^3$	$2.1 \times 10^{-22}$	$2 \times 10^{-3}$	$\sim 2$
$10^4$	$10^4$	$2.1 \times 10^{-21}$	$4 \times 10^{-3}$	$\sim 20$
$10^{4.5}$	$10^5$	$2.1 \times 10^{-20}$	$1 \times 10^{-2}$	$\sim 200$
$10^6$	$10^5$	$3.4 \times 10^{-17}$	0.3	$> 1000$

**Table 1.** Mechanical heating rates for different densities and FUV luminosities for models whose metallicity is  $Z = Z_{\odot}$ . These models span the full density and UV ranges we have explored. Almost the full range of mechanical heating rates are also covered, from quiescent discs (first row) to highly turbulent star-bursts (last row).

A simple recipe (also adopted in Paper I) for estimates of  $\Gamma_{\text{mech}}$  in a star-burst is presented in Loenen et al. (2008). One

of the main assumptions concerns the fraction of the energy of a super-nova (SN hereafter) event transferred into heating the ISM ( $\eta_{\text{trans}}$ ), which was assumed to be 10%. However,  $\eta_{\text{trans}}$  is not well known in general. The amount of turbulent energy transferred into heating the ISM, ( $\Gamma_{\text{mech}}$ ), is also related to  $\eta_{\text{trans}}$ . For this reason we consider values of  $\alpha$  ranging for 0 to 1. This range would cover most heating rates that would be a result from the full range of  $\eta_{\text{trans}}$ . As an example,  $\alpha$  could be related to the local SFR in a star-burst. In general, a higher SFR, would result in a high SN rate, thus a larger  $\alpha$  as shown in Table-1.

Moreover, we used the mechanical luminosity curves in Leitherer et al. (1999) as an independent method of estimating the amount of  $\Gamma_{\text{mech}}$  that can be disposed into the ISM. In Leitherer et al. (1999) stellar population synthesis models are used to predict spectrophotometric properties of active star-forming regions. Figures-111 to 114 in that paper, provide predictions for the mechanical luminosity over a time-span of 1 Gyr, both for an instantaneous star-burst ( $L_{\text{mech}} = 10^{40} - 10^{41} \text{ erg/s}$ ) and a continuous one ( $L_{\text{mech}} = 10^{42} \text{ erg/s}$ ). The mass of the stars formed during these two scenarios is  $10^6 M_{\odot}$ . If we assume that this occurs in a box whose size is 100 pc (the same spatial scale used in Loenen et al. (2008)), we obtain a  $\Gamma_{\text{mech}} \sim 10^{-20} \text{ erg cm}^{-3} \text{ s}^{-1}$  and  $\Gamma_{\text{mech}} \sim 10^{-22} - 10^{-21} \text{ erg cm}^{-3} \text{ s}^{-1}$  for the continuous and the instantaneous star-burst scenarios respectively. In computing those estimates, we assumed that the mechanical luminosity is fully absorbed by the ISM since they occur over a time-span of at least 50 Myr, which is much longer than the chemical time-scale.

Our final attempt to estimate  $\Gamma_{\text{mech}}$  relied on extracting the mechanical feedback from softened particle hydrodynamics simulations of dwarf galaxies (Pelupessy & Papadopoulos 2009). There the mechanical heating is computed self-consistently in the SPH code. In the left panel of Figure-2, we show the mechanical heating rate (per unit volume) as a function of the gas density of the SPH particles. It is quite comforting to note that, although the previous two methods were quite simplistic, the estimated mechanical heating rates are close to those obtained by the SPH simulation for the same density range.

## 2.2. Radiative Transfer

Two methods were used in computing the radiative transfer of the atomic and molecular lines. Those of the atomic fine-structure (hereafter FS) lines were computed self-consistently within the PDR code (see Meijerink & Spaans (2005) for the details). For these lines the temperature gradient within the slab has been taken into account.

In computing the emission of the molecular species the statistical equilibrium non-LTE radiative transfer code RADEX (Schöier et al. 2005) was used. In order to account for clouds with different depths, the various emission were computed for different  $A_V$ . This is equivalent to saying that we considered a semi-finite slab illuminated by a UV source from one side (the primary UV source). In using this approximation the UV flux from a source which could be on the other side of the truncated slab model, is ignored. Accounting for that second source would be important in the case when  $A_V$  is low ( $< 1 \text{ mag}$ ) and when the lines are optically thin. Although the the lowest  $A_V$  we considered was 5 mag, the worst case scenario even for high  $A_V$  is when the secondary UV source (from the other side) has the same strength as the primary. In this case, ignoring the secondary UV source would reduce the emission by at least half the amount. For our purposes, since we would be looking at line ratios and at clouds with  $A_V > 5 \text{ mag}$ , we expect this approximation to be

satisfactory for our purposes. Hence, for simplicity we assume that the semi-infinite slab is illuminated by a UV source from one side only. There are PDR codes which allow for a secondary UV source, for example Le Petit *et al.* (2006). An even more advanced PDR code which allows for an arbitrary 3D geometry has been developed by Bisbas *et al.* (2012).

The large velocity gradient (LVG) approximation upon which RADEX is based does not take into account a PDR temperature gradient. For the molecular species, this is not crucial, for two reasons: firstly, molecules are only abundant in regions beyond  $A_V \gtrsim 5$  mag. In those regions the molecular abundances are at least two orders of magnitude higher than those close to the surface of the PDR ( $A_V = 0$  mag). Secondly, deep into the cloud where  $A_V \gtrsim 5$  mag temperatures are practically constant, very different from the steep temperature gradients close to the PDR surface.

Although the temperature is almost constant in the molecular zone, we tried to account for the contribution of the temperature gradient of the atomic and radical zones by using a weighted average of the quantities required to compute the emission. The gas kinetic temperature and the densities of the colliding species (mainly  $H_2$ ) were weighted against the density of the species of interest. The weighted temperatures are  $\sim 3\%$  higher than the saturated kinetic temperatures in the molecular zone. This is due to higher kinetic temperatures at the surface compared to those in the molecular zone. In contrast the weighted density of the colliding species was about 5% lower than those in the molecular zone. This reflects the fact that  $H_2$  has a much lower abundance near the surface of the cloud compared to that at the molecular zone. These two counteracting effects, higher temperature and lower abundances result in a 1% increase in the emission compared to the case where no weighting was done.

The densities of the colliders are also weighted with respect to the abundances of species whose emission are being computed. The colliders considered were  $H_2$ ,  $H^+$ , He and  $e^-$ . Finally, a background radiation field corresponding to that of the current day CMB is used by RADEX. One of the assumptions we adopted, which cloud effect the outcome of the line ratios of  $^{13}CO$  to CO, is the elemental abundance of C and  $^{13}C$ . Since we opted to keep the number of parameter low for this exploratory investigation, we chose  $C / ^{13}C = 40$  for all our models, even for models with higher and lower metallicities. The actual ratio could be as high as 90 and as low as 20 in our galaxy (Savage *et al.* 2002). Since we picked a lower value, we expect that variations over the possible range would only decrease the emission of  $^{13}CO$ ; hence leading for line ratios involving  $^{13}CO/CO$  to decrease.

One of the main advantages offered by the use of RADEX (one-zone approximation) over a calculation based on the temperature gradient is the much greater speed of computation. For each model, the LVG approximation requires only one computation of the population densities. In contrast, it would have been necessary to compute the population densities for each slab of the discretized PDR when taking the temperature gradient into account.

It still remains to decide what micro-turbulence line width to use. Since most molecular line emission emanates from the shielded region where  $A_V > 5$  mag and where the gas is relatively cold, the line widths there are expected to be low. Again, here we resort to the simulations of Pelupessy & Papadopoulos (2009), where for such clouds, the velocity dispersion is on the order of few km/s. Hence, for simplicity we used a micro-turbulence line-width of 1 km/s for all our models. We considered other line widths as well but the effect on the line ratios

was negligible. We note that this line width should not be confused with the measured (observed) line-width. The measured line-width would be due to the contribution of multiple clouds along the line of sight. For extra-galactic sources, this line-width would be much larger than the micro-turbulence line-width.

As a check on the validity of using LVG models, we compared the emission grids computed with the LVG approximation to those computed by Meijerink *et al.* (2007). Although the grids in Meijerink *et al.* (2007) have been computed taking into account the temperature gradient in the PDR, they agree quite well with the ones we computed here with RADEX. As an independent check, the grids without  $\Gamma_{mech}$  agreed quite well with the ones computed by Kaufman *et al.* (1999).

### 3. Results

Atomic fine-structure and molecular emission lines are studied in order to see how mechanical feedback could affect their emission and their various line ratios. Here we present results from the reference models summarized in Table-2, and highlight some emission grids. The grids for different column densities are presented in the Appendix. We start by presenting results of the atomic lines, followed by those for molecular species. For each of the species considered we highlight the main chemical and radiative factors which effect their emission. Once we have characterized the effect of mechanical feedback on the emission of the reference models and the model grids, we proceed by highlighting trends in the line ratios which could be used as diagnostics for mechanical feedback in the ISM.

Model Name	$\log n$ ( $cm^{-3}$ )	$\log G_0$
MA1	1.0	2.0
MA2	2.0	1.0
M1	3.0	3.0
M2	3.0	5.0
M3	5.5	3.0
M4	5.5	5.0

**Table 2.** This is a list of the reference models for typical PDRs used in this paper. The models in the top part (MA1 and MA2) are particularly useful for studying the line emission of the atomic species (the FS lines). Since molecular line emission is too low to be relevant in these two low-density models, higher density models are also considered (M1 to M4). All these models are identical to the reference models from Paper I and Meijerink & Spaans (2005). M1 and M2 correspond to low-density clouds in star-bursting galaxy centres, whereas M3 and M4 correspond to much denser clouds where excitation of high density gas tracers such as HCN are possible. These models are also shown in our template grid in Fig-1.

#### 3.1. Atomic species - intensities

FS lines such as [OI] 63  $\mu m$  and [CII] 158  $\mu m$  are the dominant coolants in PDRs. High temperatures ( $> 100K$ ) are necessary to have a bright emission of those lines. Thus most of the emission originates from the surface layer of the PDR where  $N_H < 10^{21} cm^{-2}$ . The temperatures drop with increasing  $N_H$  as such column densities are optically thick for FUV photons (Hollenbach & Gorti 2009). In Figure-3 we show the integrated cooling rate as a function of depth ( $A_V$ ) for M1. From a qualitative point of view, the cooling budgets for the remaining models

are similar. The purpose of this figure is to illustrate the steep dependence of the FS cooling as a function of  $A_V$ . We also see here that the cooling due to the lowest transition of the molecular species considered adds up to less than  $\sim 1\%$  of the total cooling. For simplicity, we do not include this small contribution in the thermal balance, albeit it is not quite negligible.

**Fig. 3.** Integrated cooling rates (in  $\text{erg cm}^{-2} \text{s}^{-1}$ )  $\int_0^{A_V} \Lambda(A'_V) dA'_V$  as a function of  $A_V$  for the various cooling mechanisms included in the PDR code. The curves for the total cooling (blue with crosses) and the FS cooling curve overlap. The remaining solid curves (MS for meta-stable line cooling, RV for ro-vibrational cooling of  $\text{H}_2$ , and LyA for the Lyman-alpha cooling) are shown for completeness. The dotted curves (with filled circles) are the first rotational transitions for the molecular species computed using LVG models.

Although most of the FS emission emanates from the PDR’s surface section, the molecular zone also contributes. This contribution of the molecular zone to the FS cooling is important when considering line ratios. It depends on the location of the  $\text{C}^+/\text{C}/\text{CO}$  transition zone. A fast transition (as a function of  $A_V$ ) from  $\text{C}^+$  to C, would result in a lower abundance of  $\text{C}^+$  (thus lower emission). Usually, the  $A_V$  where the  $\text{C}^+/\text{C}/\text{CO}$  transition zone occurs is closer to the surface for PDRs with high densities than clouds with low densities. This phenomenon is described in more detail in Kazandjian *et al.* (2012). For example, in low-density PDRs the abundances of  $\text{C}^+$  ( $x_{\text{C}^+}$ ) decreases slightly from  $\sim 10^{-4}$  (at the surface) to  $\sim 10^{-5}$  in the molecular zone. However, a much greater decrease in  $x_{\text{C}^+}$  is observed in the molecular zone of medium and high-density PDRs; there  $x_{\text{C}^+}$  decreases to  $\sim 10^{-10}$ . Consequently, we expect to find higher contributions to  $\text{C}^+$  cooling from the molecular zones in low-density clouds than in high-density clouds.

A similar analysis applies to the other FS lines of C and O. For example in clouds which are highly dominated by UV radiation (see Figure-1) atomic abundances remain relatively high in the molecular zone. At the surface  $10^{-6} < x_{\text{C}^+} < 10^{-4}$  and  $x_{\text{C}} \sim 10^{-4}$  due to the high flux of FUV photons which can penetrate deep into the clouds. Hence recombination is less effective in locking the atoms into molecules. At densities  $n > 10^3 \text{cm}^{-3}$ , the FUV photons are blocked by higher columns of CO resulting in  $x_{\text{C}^+} < 10^{-8}$  and  $x_{\text{C}} < 10^{-6}$ .

**Table 3.** Critical densities and the transition (excitation) energies for the atomic FS lines and the molecular lines. The critical densities for the molecular lines displayed were computed for a kinetic temperature of 50K; whereas the one for the FS lines were computed at 500K. The values of  $n_{cr}$  are shown to give the reader an idea of the regime for the densities where the species would be at LTE or not. The symbols “L” (low), “M” (medium), “H” (high) indicate the range in density where the  $n_{cr}$  of the corresponding transition lies.

The intensity of the emission depends mainly on the chemical abundances of the species in question (discussed in the previous two paragraphs) and strongly on the kinetic temperature of the gas. Here we investigate the effect of  $\Gamma_{\text{mech}}$  on the emission, from the atomic and molecular zones, by looking at its effect on the kinetic temperature of the gas. In general we expect the emission to be enhanced as  $\Gamma_{\text{mech}}$  is introduced into a PDR. At the surface, mechanical feedback increases the temperatures at most by a factor of three, even for the highest  $\Gamma_{\text{mech}}$  considered. As an example, in the low  $G_0/n$  ( $\sim 0.01 - 10$ ) models such as MA1 and MA2, the surface temperature increases from 110 K to 300 K without mechanical heating ( $\alpha = 0$ , see Eq. 1 and Fig. 2) and from 2200 K to 4500 K for maximum  $\Gamma_{\text{mech}}$  ( $\alpha = 1.0$ ), respectively. Note that the surface of low density PDRs is a lot more sensitive to  $\Gamma_{\text{mech}}$  compared to the high density ones. Moreover, the temperature increase in the molecular zone is much greater.

For instance in the low density PDRs, we see a boost from  $\sim 10\text{K}$  to  $100\text{K}$  in MA2 and MA1 whenever  $\Gamma_{\text{mech}} = 0.1\Gamma_{\text{surf}}$ .

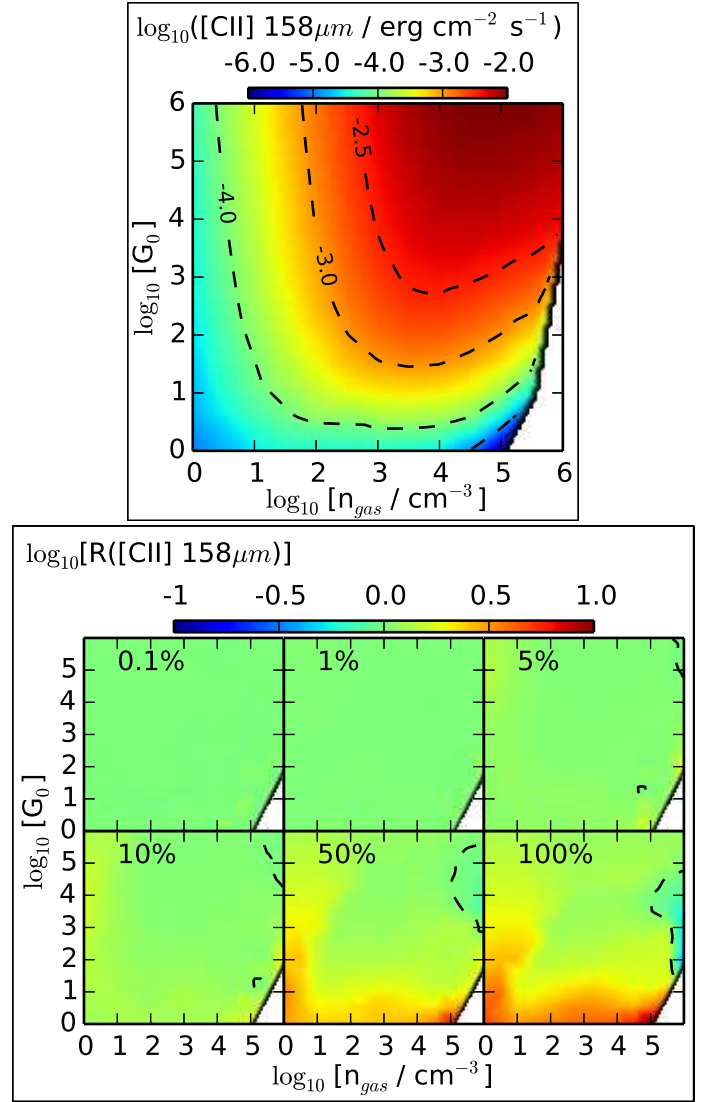

We now turn our attention to the contribution of the molecular zone to the integrated luminosity of the FS lines. In pure PDRs ( $\alpha = 0$ ) which are in the  $G_0/n \gg 1$  regime, at least 2% of the integrated luminosity comes from depths with  $A_V > 5$  mag. Since  $\Gamma_{\text{mech}}$  increases temperatures in the molecular zone, we expect the FS line emission to increase as well (this is explained in more detail in section-3.3). For instance, when  $\alpha = 0.25$  the contribution of the molecular zone increases to  $\sim 10\%$  for clouds with  $A_V = 10$  mag. For clouds with higher  $A_V$  ( $\sim 30$  mag) this contribution increases further up to 50%.

In the top panel of Figure-4, we show the emission grid of the [CII]  $158\mu\text{m}$  FS line. This grid agrees very well with that shown in Figure-3 in Kaufman *et al.* (1999). In the lower panel, we illustrate the relative changes in the emission of that same grid as a function of  $\alpha$ . We see that the [CII]  $158\mu\text{m}$  FS line emission depends weakly on  $\Gamma_{\text{mech}}$  whenever it is below  $0.5\Gamma_{\text{surf}}$  ( $\alpha < 0.5$ ). Whenever  $\alpha \geq 0.5$  low density PDRs such as MA1 and MA2 show an increase in the emission by up to a factor of two. The mid- and high-density PDRs whose  $G_0 > 10^2$  are hardly effected. The emission of [OI]  $63\mu\text{m}$ , [CI]  $369\mu\text{m}$ , and [CI]  $609\mu\text{m}$  exhibit a stronger dependence on  $\Gamma_{\text{mech}}$ . These grids are shown in Figure-A1 in Appendix-A.

As a basis for discussion, we first highlight some of the main features of the FS emission grids in the absence of any  $\Gamma_{\text{mech}}$  contribution. (1) Emission intensities increase as  $G_0$  increases (see the top panels of Figure-4 and Figure-A1). This is caused by the ability of the FUV photons to penetrate deeper into the cloud at fixed  $n$  but higher  $G_0$ , thus leading to a thicker atomic region. (2) Emission peaks near the critical densities of the lines ( $n_{\text{cr}}$  hereafter). Those  $n_{\text{cr}}$  are around  $10^3\text{cm}^{-3}$  with the exception of the critical density of the [OI] line which lies in the high density region. Both excitation energy  $E_{ul}/k_B$  and  $n_{\text{cr}}$  for all the lines are listed in Table-3. (3) The emission intensities range from  $10^{-6}\text{erg cm}^{-2}\text{s}^{-1}$  to  $10^{-2}\text{erg cm}^{-2}\text{s}^{-1}$ , spanning four orders of magnitude. This is significantly brighter than the molecular emission (see section-3.3), which peaks at  $10^{-5}\text{erg cm}^{-2}\text{s}^{-1}$ . The range in the intensities of the atomic fine-structure lines is narrower than that of the molecular lines. (4) When  $\Gamma_{\text{mech}}$  is introduced the emission is enhanced for  $n < n_{\text{cr}}$ ; the opposite is observed for  $n > n_{\text{cr}}$ . This is particularly valid for the neutral and atomic species (see the bottom panels of Figure-4 and Figure-A1).

Here we focus on the last point mentioned in the previous paragraph. Particularly we try to determine the reason causing the different behaviour of the emission for  $n < n_{\text{cr}}$  vs  $n > n_{\text{cr}}$ . The boost in the emission could be due to an increase in temperature, or in abundance, or both. By analysing the chemistry we see that the dominant reactions remain the same (up to  $\alpha \sim 0.1$ ) for  $n < n_{\text{cr}}$ . Moreover there are no fundamental changes in the abundances for  $n < n_{\text{cr}}$ . This ties the emission boost to the increasing amounts of  $\Gamma_{\text{mech}}$  that raise the gas temperature, particularly in the molecular region.

Let us now consider the part of the parameter space in the grid where  $n > n_{\text{cr}}$ . The emission tends to decrease whenever  $\alpha > 0.1$ . The only exception to this occurs in the emission grid for the [OI]  $63\mu\text{m}$  line (see rightmost panel in the bottom row of Figure-A1). At such densities, O maintains a much higher abundance than  $\text{C}^+$  in the molecular zone. Hence the strongest decrease is seen for the two neutral carbon lines [CI]  $369\mu\text{m}$  and [CI]  $609\mu\text{m}$  (see left and middle panels of Figures-A1) whereas the opposite is observed for [OI]  $63\mu\text{m}$ . We will discuss each of those below.

**Fig. 4.** **[top]** The reference grid for the [CII]  $158\mu\text{m}$  line emission for PDRs without mechanical heating. **[bottom]** [CII]  $158\mu\text{m}$  line emission corresponding to different values of  $\alpha$  labelled at the top of each panel. Each model in the grid has an additional amount of heating introduced to its energy budget. The added  $\Gamma_{\text{mech}}$  is in terms of a percentage of the surface heating (as explained in the methods section). Each grid shows the percentage change (increase or decrease) in emission relative to that in the reference grid in the **top** panel. For instance, when  $\Gamma_{\text{mech}} = 0.5\Gamma_{\text{surf}}$  ( $\alpha = 0.5$ ) (panel with the 50% label), the emission in MA1 is enhanced by a factor of  $\sim 3$ . A decrease in emission is observed only when  $\Gamma_{\text{mech}} > 0.5\Gamma_{\text{surf}}$  to the right of the contour line at M4. We define the relative change as  $R = I(\alpha)/I(\alpha = 0)$ , where  $I(\alpha)$  is the emission intensity of the line at a specific value of  $\alpha$ . Here and in all such subsequent plots the dashed contour line traces  $R = 1$ . On this line the emission with and without extra heating are the same. In other words, models on this line experience no change in the emission because of  $\Gamma_{\text{mech}}$ . In general 'redder' regions correspond to enhanced emission, whereas 'bluer' regions indicated regions where emission are suppressed.

The high density region of the [CII]  $158\mu\text{m}$  grid reveals a decrease in the emission only in extreme cases ( $\alpha > 0.5$ ). This is seen most clearly to the right of the dashed line in the panels

for  $\alpha = 0.1, 0.5$  and 1 in Figure-4). This is simply because  $C^+$  becomes un-abundant at high densities ( $n \gtrsim 10^5 \text{ cm}^{-3}$ ).

The emission of [OI]  $63 \mu\text{m}$  is more interesting but less trivial to explain, since it is the result of an interplay between the cooling due to the FS lines and the additional  $\Gamma_{\text{mech}}$ . We have already mentioned that [OI]  $63 \mu\text{m}$  is the dominant cooling line in all the models. As  $\Gamma_{\text{mech}}$  is added more cooling is required to maintain a thermal balance. This occurs by increasing the gas temperature throughout the PDR which in turn boosts the total cooling rate by increasing the [OI]  $63 \mu\text{m}$  emission. At the densities of interest here ( $n > 10^4 \text{ cm}^{-3}$ ) and with  $\alpha > 0.5$ ,  $x_{\text{O}}$  decreases from  $10^{-4}$  to  $10^{-8}$  in the molecular zone due to the dominant reaction of O with OH. Notwithstanding the steep decrease in  $x_{\text{O}}$ , the [OI]  $63 \mu\text{m}$  emission increases because of the much higher temperatures.

Finally, the reduction in the [CI] emission (at high densities) when  $\Gamma_{\text{mech}}$  is introduced, is due to  $x_{\text{C}}$  decreasing by an order of magnitude in the atomic region of the PDR; dropping from  $\sim 10^{-4}$  to  $\sim 10^{-5}$  where most of the emission comes from. We discuss this for an extreme PDR with conditions typical for an extreme star-burst ( $n = 10^6 \text{ cm}^{-3}$  and  $G_0 = 10^6$ ). There the emission decrease is greatest. This decrease is due to the reduced production rate (by one order of magnitude) of C through the neutral-neutral reaction of H with CH. Moreover, higher abundances of  $\text{H}_2$  in the atomic region enhance the radiative association reaction of C with  $\text{H}_2$ , leading to a faster destruction of C. These two processes results in a reduction of  $x_{\text{C}}$  throughout the PDR leading to lower emission.

The different dependence on  $\Gamma_{\text{mech}}$  throughout the grids of the lines encourage us to look in detail at the various combinations of line ratios in an attempt to identify effective diagnostics for  $\Gamma_{\text{mech}}$ . We first summaries the most important model emission features that play a role in determining the ratios:

- For pure PDRs (without  $\Gamma_{\text{mech}}$ ) we can safely say that the majority of the FS emission are from the surface of the cloud and up to  $A_V = 10$  mag. Particularly, [OI]  $63 \mu\text{m}$  and [CII]  $158 \mu\text{m}$  saturate at  $A_V \sim 5$  mag.
- When  $\Gamma_{\text{mech}}$  is introduced, the molecular zone contributes increasingly to the integrated emission of the lines, especially those of [CI]. When  $n < n_{\text{cr}}$  more than half of the emission in these lines is from the molecular zone. Hence, line ratios might depend on the column densities of the PDRs considered.
- As  $\Gamma_{\text{mech}}$  increases, emission of the FS lines for clouds with  $n < n_{\text{cr}}$  increases; whereas it tends to decrease above that density (except for [OI]).

### 3.2. Atomic species - line Ratios

So far we have touched upon the intensities of the emission of FS lines. What actually matters is the relative enhancement of one emission line compared to another (i.e the line ratio); this is a commonly used technique since understanding line ratios sheds insight on the underlying excitation mechanism(s) of such emission. In Figure-5 we show (for the reference models) all the possible combinations of line-ratios of the FS lines that we considered. The analogous figures for metallicities either higher or lower than solar are presented in the Appendix (see Figure-A2). We note that the line ratios apply to fixed cloud sizes ( $A_V = 10$  mag).

The very low-density models (MA1 and MA2) show a distinctive response to  $\Gamma_{\text{mech}}$  in comparison to the rest of the models. Only in these two models, some of the line ratios (expressed

**Fig. 5.** Fine-structure line ratios for different values of  $\Gamma_{\text{mech}}$  ( $Z = Z_{\odot}$ ) for the reference models.

on log-scales) change sign i.e. the ratio changes from being below unity to above unity or vice-versa due to one line becoming brighter than the other.

For instance, in MA1, the ionized to neutral atomic carbon line ratio [CII]  $158 \mu\text{m}/[\text{CI}] 369 \mu\text{m}$  shows a very nice dependence on  $\Gamma_{\text{mech}}$ . It decreases from  $\sim 15$  to unity as  $\Gamma_{\text{mech}}$  increases. A similar behaviour is observed for MA2, but the ratio saturates to  $\sim 3$  at high  $\alpha$ . Another interesting line ratio is that of neutral oxygen to neutral carbon ([OI]  $63 \mu\text{m}/[\text{CI}] 369 \mu\text{m}$ ), which exhibits a very strong response to  $\Gamma_{\text{mech}}$ . The ratio decreases as  $\alpha$  increases. The reason for this is the fact that the [CI]  $369 \mu\text{m}$  line is enhanced (and becomes stronger than the [OI]  $63 \mu\text{m}$  line) due to the low energy of the [CI]  $369 \mu\text{m}$  transition (24 K) compared to the 228 K of the [OI]  $63 \mu\text{m}$  line. Hence, the [OI]  $63 \mu\text{m}$  emission remains restricted to the surface, whereas the total emission of [CI]  $369 \mu\text{m}$  gets a significant contribution

from the deeper molecular interior. This line ratio decreases by approximately a factor of ten for MA1 (from  $\sim 20$  to  $\sim 3$ ) when  $\Gamma_{\text{mech}}$  is as low as 5% of the surface heating. A less distinctive behaviour is observed in MA2, where the line ratio decreases from  $\sim 2$  to  $\sim 1$  and increases again to above 2 for  $\alpha = 0.5$ . In MA1, the ratio of the principal cooling lines, neutral oxygen to singly ionized carbon ([OI]  $63\mu\text{m}$ /[CII]  $158\mu\text{m}$ ), has a weak dependence on  $\Gamma_{\text{mech}}$ . It increases only for extreme mechanical heating rates corresponding to  $\alpha = 0.5$ . More interestingly, in MA2 the ratio has a stronger dependence of  $\Gamma_{\text{mech}}$  approaching unity (from  $\sim 0.3$ ) as  $\alpha$  increases. This is explained by the fact that as  $\alpha$  increases, temperatures increase as well. Since  $x_{\text{O}}$  is about 100 times higher in the molecular zone than  $x_{\text{C}}$ , the [OI]  $63\mu\text{m}$  emission increases. This occurs despite the fact that the transition energy for the [CII]  $158\mu\text{m}$  line is less than half that of the [OI]  $63\mu\text{m}$  line. A similar behaviour is observed in M1, but there the ratios increase from 1 to  $\sim 3$ .

The neutral carbon-carbon line ratio [CI]  $369\mu\text{m}$ /[CI]  $609\mu\text{m}$  is particularly interesting since it involves FS lines of the same atomic species; hence the line ratio depends purely on the radiative properties of the lines and neither on the chemistry nor the column density. In MA1, we see a steady increase in the ratio from 1 to  $\sim 5$  for  $\alpha = 0.05$ . This can be easily explained. As  $\Gamma_{\text{mech}}$  causes temperatures to rise, the upper levels become more populated, so that the third level involving the [CI]  $369\mu\text{m}$  line becomes brighter than [CI]  $609\mu\text{m}$ . For a detailed discussion on level populations see section-3.3.

The C[II]  $158\mu\text{m}$ /[CI]  $609\mu\text{m}$  and [OI]  $63\mu\text{m}$ /[CI]  $609\mu\text{m}$  ratios do not exhibit any very interesting dependence on  $\Gamma_{\text{mech}}$ . They are shown just for completeness.

The high-density models M1 to M4 exhibit a slow monotonous (either increasing or decreasing) dependence on  $\Gamma_{\text{mech}}$ . The ratios in these models are generally  $\gtrsim 10$  even for  $\alpha = 0$ . This is also true for extreme mechanical heating rates  $\alpha = 1$  (except for [OI]  $63\mu\text{m}$ /[CII]  $158\mu\text{m}$  in M1). Unlike the low density models, models M1 to M4 exhibit a jump in the line ratios only when  $\alpha \gtrsim 0.5$ .

In summary, what we have found in this section that [CII]  $158\mu\text{m}$ /[CI]  $369\mu\text{m}$ , [OI]  $63\mu\text{m}$ /[CI]  $369\mu\text{m}$  and [CI]  $369\mu\text{m}$ /[CI]  $609\mu\text{m}$  are good diagnostic line ratios for low density clouds. One can use those lines to constrain  $\Gamma_{\text{mech}}$  if the density,  $G_0$  and the  $A_V$  of the object are known. Those line ratios show a stronger dependence on  $\Gamma_{\text{mech}}$  at higher or lower metallicities as well, except in models at  $Z = 0.1Z_{\odot}$  (see Figure-A2). However, further investigation is needed in-order to see if atomic line ratios are good diagnostics of mechanical feedback for the whole range in density,  $G_0$  and  $A_V$ .

In addition to the reference models, the grids of the line ratios from which those models were picked are presented in Appendix-A (see Figure-A3).

### 3.3. Molecular species

The molecular emission lines were computed with LVG models, unlike those of the atomic species which were computed within the discretized PDR. We utilized the LVG code RADEX (Schöier *et al.* 2005) in computing all the emission intensity grids. In this paper, we have limited ourselves to the rotational line emission from CO,  $^{13}\text{CO}$ ,  $\text{HCO}^+$ , HCN, HNC, CS, and CN.

We first present an analysis that is common to most of the molecular lines considered. In pure PDRs ( $\alpha = 0$ ), the gas temperatures in the molecular region are very low ( $10 \sim 15\text{K}$ ) and vary little within the grid (see the grids corresponding to  $\alpha = 0$  in Appendix B for all the molecular species). Thus whenever the

gas density of a cloud is below the critical density ( $n_{\text{cr}}$ ) of the line considered, the chemistry determines the shape of the contours in the emission grid. There the contour lines are independent of  $G_0$  and appear as almost vertical lines. Also in the absence of  $\Gamma_{\text{mech}}$ , the emission contours follow the shape of the temperature contours of the molecular region. This is particularly valid in the case of the high- $J$  transitions. However, when we introduce  $\Gamma_{\text{mech}}$ , the chemistry is altered significantly along with the gas temperature. This causes the emission to increase by orders of magnitude (cf. the figures for CO with  $\Gamma_{\text{mech}}$  in the Appendix).

On the other hand, for densities above  $n_{\text{cr}}$ , the contours in the emission grids depend mainly on temperature. This is not surprising, as we may demonstrate by considering a simple two level system. The ratio of the upper population density ( $x_2$ ) to the lower one ( $x_1$ ) at equilibrium is (Draine 2010):

$$\frac{x_2}{x_1} = \frac{1}{1 + n_{\text{cr}}/n_{\text{col}}} \frac{g_2}{g_1} \exp\left(-\frac{T_{12}}{T_{\text{kin}}}\right) \quad (2)$$

where  $n_{\text{col}}$  is the density of the colliding species (mainly  $\text{H}_2$ ),  $g_1$  and  $g_2$  are the degeneracies of the lower and upper levels respectively and  $T_{12}$  is the energy difference of the two levels in Kelvins ( $E_{12}/k_b$ ). For simplicity, we assume  $n_{\text{col}} = n(\text{H}_2)$ , and also ignore a second term on the right involving the radiation temperature ( $T_{\text{rad}}$ ) that introduces only minor changes in the LVG treatment (since  $T_{\text{rad}} = T_{\text{cmb}} \ll T_{\text{kin}}$  in general).

When  $n_{\text{col}} \gg n_{\text{cr}}$ , this equation reduces to :

$$\frac{x_2}{x_1} = \frac{g_2}{g_1} \exp\left(-\frac{T_{12}}{T_{\text{kin}}}\right) \quad (3)$$

which is independent of the gas density, and depends only on the kinetic gas temperature. Also, when  $n_{\text{col}} > n_{\text{cr}}$ , all the lines are thermalized, and the excitation temperature is effectively equal to the gas temperature. Although these equations are for a two-level system, they provide a general idea of what might be happening in a multi-level systems (which might include multiple colliding species whenever the rates are available).

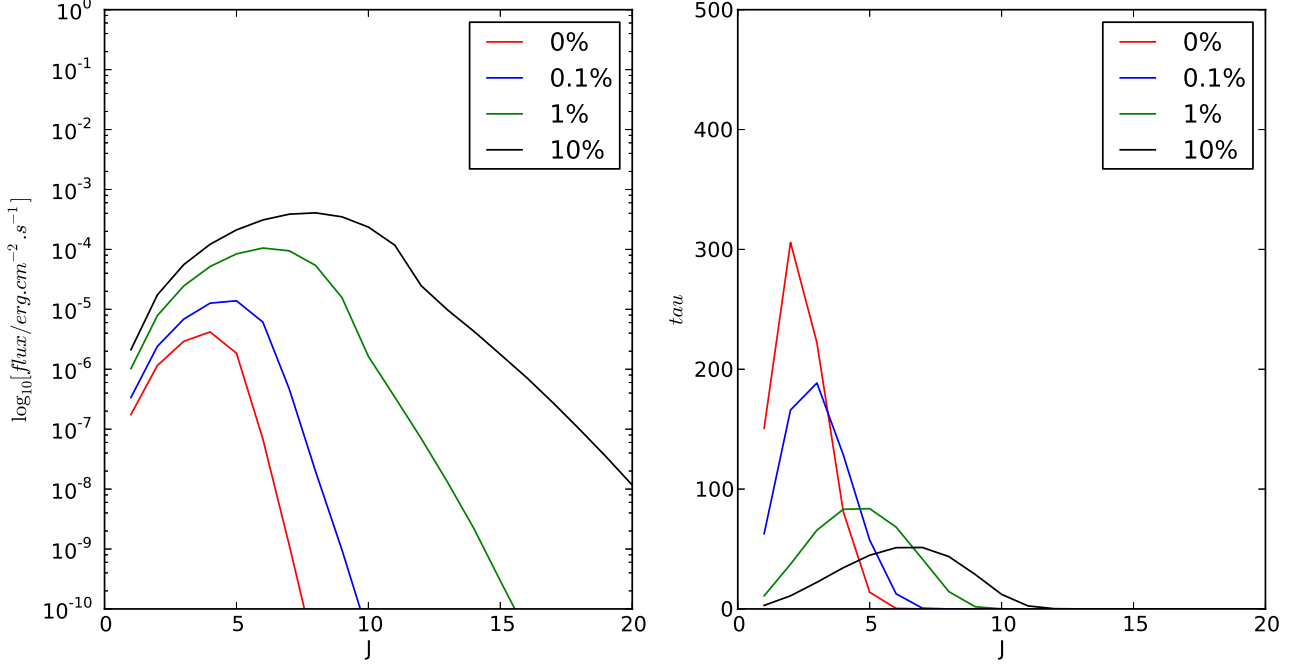

As  $\Gamma_{\text{mech}}$  is introduced, the higher transitions gain prominence since relative temperature increases are high. This in turn leads to increased high-level populations (see the left panel of Figure-6). Another way to look at the pumping of the higher levels is by looking at the collision rate coefficients  $K_{12}$  and  $K_{21}$ . Ignoring degeneracies, those two are related via  $K_{12} \sim K_{21} \exp(-T_{12}/T_{\text{kin}})$ .

Another interesting common feature is the optical depth at the line centre,  $\tau_0$ . We observe that it decreases as a function of increasing  $\Gamma_{\text{mech}}$ . As temperatures increase, more levels get populated leading to smaller optical depths. These are shown in Figure-6, which shows the CO ladder along with curves for  $\tau_0$  for a range in  $\Gamma_{\text{mech}}$ . In the right panel, the trend in  $\tau_0$  is clearly visible.

### CO and $^{13}\text{CO}$

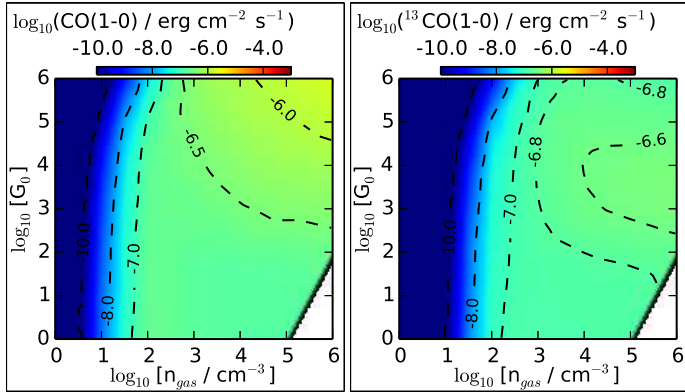

CO is the second most abundance molecule in the ISM after  $\text{H}_2$ . Since the critical density of the CO(1-0) rotational line is moderate (see Table-3), it is a good tracer of molecular gas with average densities. The critical densities increase gradually as we go higher up the CO ladder, reaching  $\sim 10^{6.5} \text{cm}^{-3}$  for the 16-15 transition<sup>2</sup>. In Figure-7 we show the grids for CO  $J=1-0$  emission. In Figure-8, we show the relative increase/decrease in CO

<sup>2</sup> The critical densities depend only lightly on temperature. For instance  $n_{\text{cr}}$  for the 16-15 transition changes only by 5% as the gas temperature changes from 10K to 1000K

**Fig. 6.** CO ladders for a PDR model with  $n = 10^3 \text{ cm}^{-3}$  and  $G_0 = 10^3$  for different values of mechanical heating. The numbers in the legend correspond to  $\Gamma_{\text{mech}}$  in terms of the surface heating. **(left)** CO line intensities as a function of the rotational level  $J$ . Notice the boost in the intensities is much larger at high- $J$  compared to low- $J$ . **(right)** Optical depth at the line centres ( $\tau_0$ ) for the same lines. The optical depth generally decreases as a function of increasing  $\Gamma_{\text{mech}}$ , but the most significant effect is that the low- $J$  CO lines become optically thinner with  $\tau_0 \sim 1$ .

$J=1-0$  emission as a function of  $\Gamma_{\text{mech}}$ . The analogous grids for the CO  $J=2-1$ , 3-2, 4-3, 6-5, 7-6, 10-9 and 16-15 transitions are presented in Figure-B1 (and a subset of those for the  $^{13}\text{CO}$  lines) are displayed in Figure-B2. We note that we will be using  $^{12}\text{CO}$  and CO interchangeably in referring to carbon monoxide.

**Fig. 7.** Emission intensity grids of CO( $J = 1 - 0$ ) and  $^{13}\text{CO}$ ( $J = 1 - 0$ ) transitions for the 1D-PDR models. The emission of the models in the grid correspond to an  $A_V = 10$  mag, which amounts to a column density of H,  $N_H \sim 10^{22} \text{ cm}^{-2}$  at solar metallicity. The intensities were computed using the RADEX LVG code. A line-width of  $1 \text{ km s}^{-1}$  was used. No mechanical heating is added for the models in this grid. This is used as a reference grid for the ones in which  $\Gamma_{\text{mech}}$  is introduced (see Fig-8).

**Fig. 8.** Relative change in the emission of the CO  $J=1-0$  rotational line for different values of  $\Gamma_{\text{mech}}$ . The colours in the panels correspond to the relative change of the emission with respect to the reference grid in the left panel of Figure-7. See also the caption of Fig.4.

At low densities ( $n < 10 \text{ cm}^{-3}$ ), the emission of CO is very weak ( $\sim 10^{-10} \text{ erg cm}^{-2} \text{ s}^{-1}$ ) compared to emission at mid- to high densities ( $n > 10^3 \text{ cm}^{-3}$ ). This is obvious in Fig.-B2. As was mentioned also earlier, we notice that at such low densi-

ties the emission contours show almost no dependence on  $G_0$ . This is simply explained by the fact that there are few collisions to excite the upper rotational levels, and that the background dust emission (which is only weakly dependent on  $G_0$ ) is dominating. Another contributing factor is the low gas temperature ( $\sim 10$  K) in the molecular zone. On the other hand at mid- and high-densities, where  $n \gtrsim n_{cr}$  of CO( $J = 1-0$ ), we start seeing a strong dependence of these emission on  $G_0$ .

In general the emission intensity is positively correlated with  $\Gamma_{mech}$ , i.e. it increases with increasing  $\Gamma_{mech}$  (see Figs.-8, B1,B2). The only exception occurs at some of the high density regions in the CO(1-0) and  $^{13}\text{CO}$  grids. We can see such a behaviour in the upper right corner of the CO grids when  $\alpha = 0.5$  and 1. In the  $^{13}\text{CO}$  grids the emission decrease is clearest (and covers a larger part of the grid), for example see the  $J=1-0$ ,  $J=2-1$  and  $J=3-2$  grids in Fig.-B2.

In well-irradiated, low-density regions ( $n < n_{cr}$  and  $G_0 > 10$ ), the emission increases up to two orders of magnitude (see red regions in Figure-8). This is caused by (1) a rise in the temperature induced by  $\Gamma_{mech}$ , and ; (2) a higher abundance of CO (and  $^{13}\text{CO}$ ), causing a double increase. The abundance of CO is boosted because its is accelerated via the reaction  $\text{H} + \text{CO}^+ \rightarrow \text{CO} + \text{H}^+$ .

At the higher densities ( $n > n_{cr}$  and  $\gg n_{cr}$ ) the response to  $\Gamma_{mech}$  becomes weaker. More than one factor contributes to this. From the thermal perspective the temperatures in the molecular regions are already high ( $\sim 50$  to  $100$  K). This is due to the tight coupling between dust and gas. Hence the relative increase in the gas temperature is small, in contrast to what happens in the low-density models. Another contributing factor is the decrease in the abundance of CO. In the absence of  $\Gamma_{mech}$ , most C atoms are locked in CO molecules. For extreme  $\Gamma_{mech}$  ( $\alpha \geq 0.5$ ) the abundance of most molecules, including  $\text{H}_2$ , decreases drastically (Kazandjian *et al.* 2012); leading to  $x_{\text{CO}}$  lower by almost 3 orders of magnitude (from  $\sim 10^{-4}$  to  $\sim 10^{-7}$ ).

Although we would suspect that the higher temperatures (due to  $\Gamma_{mech}$ ) would lead to enhanced emission, the reduced abundance and column density of CO counteracts that enhancement. These two effects combined lead to a small relative increase in emission. As an example, for low densities an increase in the emission by one order of magnitude is easily attained for  $\alpha = 0.01$ . On the other hand an  $\alpha = 0.1$  is required to enhance the CO emission by the same factor in the high density region of the grids (cf. bottom-left panel of Figure-8). The only exception where a decrease in the emission is observed occurs in the CO(1-0) line. This is not surprising, since in looking at the left panel of Figure-6 we see that the 1-0 transition is weakly effected by  $\Gamma_{mech}$  (compared to the higher transitions). So a reduced  $N(\text{CO})$  leads to lower emission of the 1-0 line.

A similar behaviour is observed for the  $^{13}\text{CO}$  emission which is, however, more sensitive to  $\Gamma_{mech}$  than  $^{12}\text{CO}$ . In particular, as  $\Gamma_{mech}$  increases, the mid- and high-density regions show a stronger decrease in the emission of the first three  $J$  transitions. This decrease is due to a reduced  $N(^{13}\text{CO})$  and an already low optical depth.  $N(^{13}\text{CO})$  is about five times lower than  $N(^{12}\text{CO})$ . Moreover the Einstein A coefficients of  $^{13}\text{CO}$  are about 20% lower than those of  $^{12}\text{CO}$ . Hence the upper levels, which are mainly excited collisionally, are de-populated less frequently, and a higher upper-level population density is maintained. We see that these two factors lead to the reduced optical depth of  $^{13}\text{CO}$ . At mid- and high-densities  $N(^{13}\text{CO})$  decreases as  $\alpha$  increases. Since the optical depth is already low, it neither plays a significant role in blocking the emission nor in enhancing the emission by allowing “trapped” radiation to escape from the

cloud; this is also true when the cloud becomes more transparent as  $\alpha$  increases. Consequently, since intensity is proportional to the column density of the emitting species, a decrease in  $N(^{13}\text{CO})$  results in lower emission. On the other hand, the  $J > 3 - 2$  transitions show enhanced emission all over the grid. This occurs despite the reduced column densities of  $^{13}\text{CO}$ . High kinetic temperature due to  $\Gamma_{mech}$  enhances the strong pumping of the associated level populations; eventually, this counteracts the effect of the reduced  $N(^{13}\text{CO})$  on the emission.

Although the generic behaviour of the CO and  $^{13}\text{CO}$  grids are similar, the differences among them are interesting enough to have a closer look at their line ratios. Especially for ones involving the low- $J$  lines where the  $^{13}\text{CO}$  lines are optically thin.

In Fig. 9, we show the line ratios for our reference models. These ratios include transitions for lines within the CO ladder (left panel), the  $^{13}\text{CO}$  ladder (middle panel), and the  $^{13}\text{CO}$  to  $^{12}\text{CO}$  line ratios (right panel). The ratios between high- $J$  and low- $J$  transitions show a strong dependence on  $\Gamma_{mech}$ . For example, in M3 the CO(16-15)/CO(1-0) ratio changes abruptly from  $\leq 0.1$  to  $> 100$  when  $\alpha > 0.05$ . A similar behaviour is observed for the corresponding  $^{13}\text{CO}$  ratio. In Fig. 6, we see that the optical depth of  $J = 16-15$  CO is almost unaffected as  $\Gamma_{mech}$  increases, whereas that of the  $J = 1-0$  line decreases rapidly from  $\sim 100$  to  $\sim 1$ . The opposite is observed when it comes to the intensity, where the  $J = 16-15$  CO line emission increases by  $\sim$  four orders of magnitude. This explains the huge increase in the ratio of those lines. This line ratio along with the ratio CO(16-15)/CO(10-9) are the only ones (among the ratios we looked at) that show a significant change for the high-density model M5 (see the top row of the middle panel in Figure-9).

In medium- to high-density models, ratios involving low- $J$  transitions are less sensitive to  $\Gamma_{mech}$ . Those ratios are almost constant in the high density models, since the lines are thermalized and the population densities do not change relative to each other. However in the low- and medium-density models MA1, MA2, and M1 the CO(4-3)/CO(1-0) ratio might be a good diagnostic for  $\Gamma_{mech}$ . In MA1 we see that this line ratio increases by a factor of  $\sim 10$  (as well as the corresponding  $^{13}\text{CO}$  ratio). Because these are ratios within the same species, the increase is a pure measure of the radiative properties of the specie. As in the cases of MA1 and MA2, we are in the non-LTE phase. As the temperature increases, the upper levels are populated faster leading to stronger emission in e.g. the CO(4-3) line, which drives up the ratio.

The most interesting and useful behaviour of the  $^{13}\text{CO}/^{12}\text{CO}$  (right panel of Fig.-9) occurs in the high density models M3 and M4. The ratios decrease monotonously from  $\sim 0.5$  (for  $\alpha = 0$ ) to  $\sim 0.1$  (for  $\alpha = 1$ ).

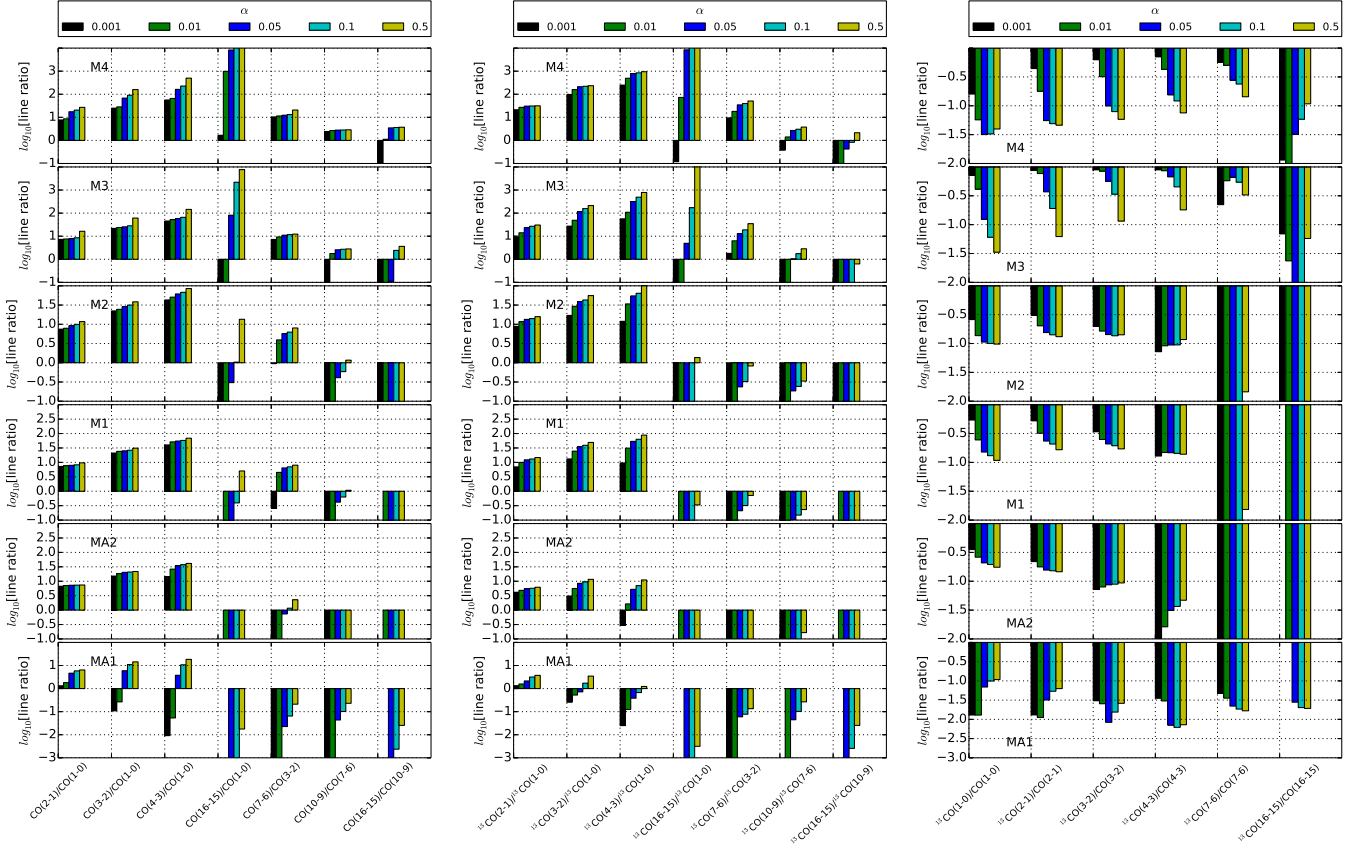

We showed previously that the optical depth of CO decreases with increasing  $\alpha$ . Also  $^{13}\text{CO}$  is optically thin in general. So for column densities corresponding to  $A_V > 10$  mag, we expect to have a steeper dependence of the line ratios of CO and  $^{13}\text{CO}$  on  $\Gamma_{mech}$ .

We summarize the main results of this section by emphasizing that in low density PDRs, the ratios of high- $J$  to low- $J$  emission lines of CO and  $^{13}\text{CO}$  might be useful diagnostics for  $\Gamma_{mech}$ . The line ratio of  $^{13}\text{CO}$  with its isotopologue CO are good diagnostics for  $\Gamma_{mech}$  in high-density PDRs. They show a strong and clear trend.

### HCN and HNC

HNC and HCN are linear molecules with very similar radiative properties in the infra-red regime. Both have (a) large dipole

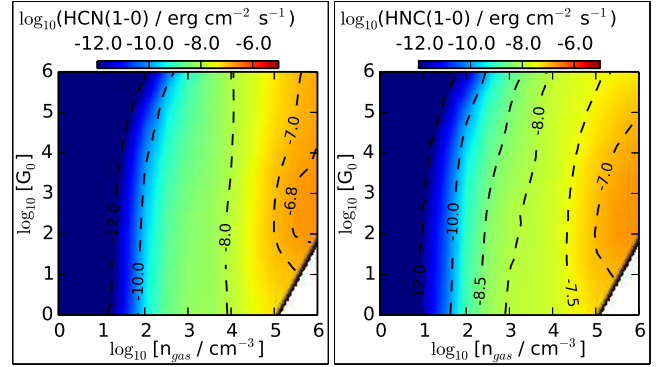

**Fig. 9.** line ratios of CO and  $^{13}\text{CO}$  for different amounts of  $\Gamma_{\text{mech}}$  ( $Z = Z_{\odot}$ ) for the reference models.

moments (3.05 and 2.98 respectively (Botschwina et al. 1993)). This allows both of them to be easily observed (b) both have high critical densities  $> 10^5 \text{ cm}^{-3}$  for the 1-0 transition (see Table-3). This renders them as good tracers for high-density molecular gas. In this paper, we consider the rotational transitions from  $J = 1 - 0$  up to  $J = 4 - 3$ , which are commonly observed. Since the emission of these lines is very sensitive to temperature changes, they might be useful in identifying molecular clouds dominated by mechanical feedback. In Paper I we studied the column density ratios of the two species. We showed that HCN becomes more abundant than HNC as  $\Gamma_{\text{mech}}$  increases. Here we study the effect of  $\Gamma_{\text{mech}}$  on the emission of these two species and their ratios.

In the absence of any  $\Gamma_{\text{mech}}$  the emission grids show a very weak dependence on  $G_0$ , as compared to their dependence on  $n$ . This dependence is illustrated in Figure-10. This kind of dependence is generic to cases where the gas density is (much) lower than the critical density of the line considered; which is also the case here.

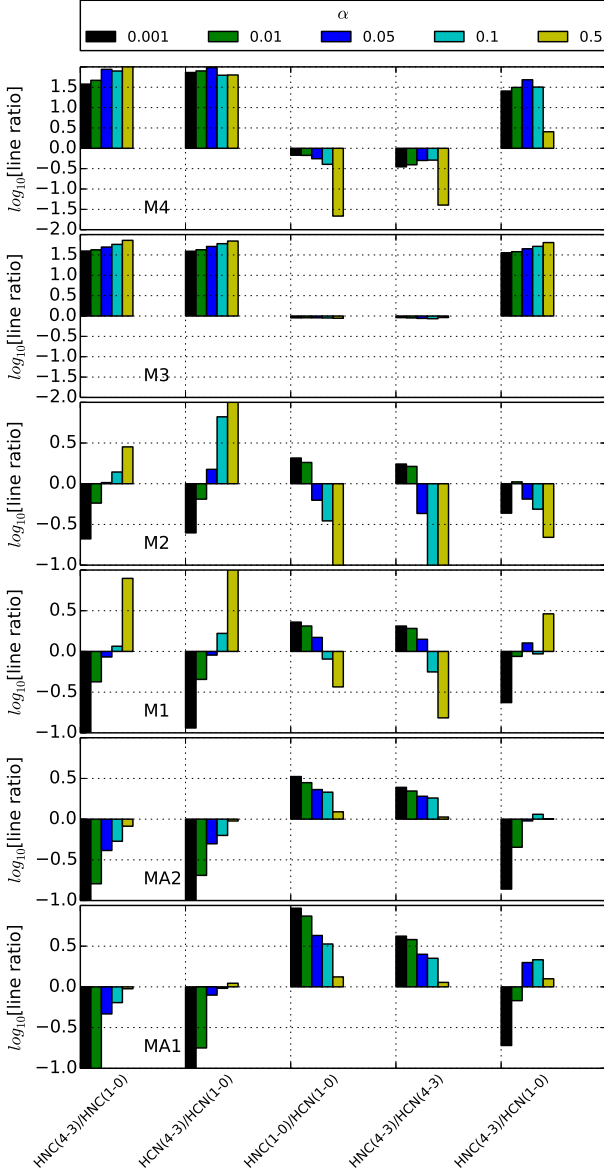

In contrast to the weak dependence on  $G_0$ , the dependence on  $\Gamma_{\text{mech}}$  is quite strong. The enhancements in the emission of HCN are stronger than those of HNC the bottom two rows of Figure-B3). This is simply because HCN becomes more abundant than HNC. The main channel through which the conversion occurs is via the reaction  $\text{H} + \text{HNC} \rightarrow \text{H} + \text{HCN}$  (see Meijerink et al. 2011, for a more elaborate discussion on the chemistry). This process becomes dominant for  $T_{\text{kin}} > 150\text{K}$  in the molecular region (Schilke et al. 1992), which is achieved when  $\alpha > 0.1$ . Below that threshold in  $\alpha$ , HNC is equally destroyed via ion-neutral reactions with  $\text{H}_3\text{O}^+$ , especially at low densities. Another

**Fig. 10.** HCN and HNC emission of the 1-0 line in the absence of  $\Gamma_{\text{mech}}$  ( $Z = Z_{\odot}$ ).

contributing factor to the increase in the abundance of HCN is its efficient formation via the neutral-neutral reactions with  $\text{H}_2$ . For completeness's sake, we note that the relative change in the emission of the  $J = 4 - 3$  line is stronger than that of the 1-0 line for reasons discussed in section-3.3.

In Fig.-11 we show the line ratios considered for HCN and HNC. Transition ratios such as  $\text{HNC}(4-3)/\text{HNC}(1-0)$  and  $\text{HCN}(4-3)/\text{HCN}(1-0)$  behave as expected (first two columns in the figure): with increasing  $\alpha$ , they increase as well (since the higher levels are populated more easily at higher temperatures). In M1 and M2, the ratio increases quite fast linearly in log scale. Unfortunately, in M3 and M4 the ratios are almost constant and are thus of little use as a diagnostic for high-density PDRs.

**Fig. 11.** Various line ratios of HNC and HCN as a function of  $\Gamma_{\text{mech}}$  ( $Z = Z_{\odot}$ ) for the reference models.

Again in M1 and M2, the inter-species ratios HNC(1-0)/HCN(1-0), HNC(4-3)/HCN(4-3) and HNC(4-3)/HCN(1-0) are strongly dependent on  $\Gamma_{\text{mech}}$ . We see that for  $\alpha = 0.5$ , the ratio HNC(1-0)/HCN(1-0) drops from  $\sim 2$  to  $\sim 0.3$ . This is caused primarily by the difference in column densities caused by the chemical effects discussed above. Since those ratios depends monotonously on  $\alpha$  (see M2 in Figure-11), we may consider them as a good diagnostic for such PDRs. This is not the case for M3 and M4. The line ratios have a weaker dependence on mechanical heating whenever  $\alpha < 0.1$ . However an abrupt decrease (from  $\sim 0.3$  to  $< 0.01$ ) is observed for  $\alpha \gtrsim 0.5$ .

Interestingly enough at metallicities typical for galactic centre regions ( $Z = 2 Z_{\odot}$ ), clouds such as M4 show a significant dependence on  $\alpha$  (see Figure-B4). This is simply a result of the fact that a higher metallicity implies a higher column density of

the gas and the species in question. In such situations, fluctuations of the abundances in the radical region play a minor role.

In summary, line ratios such as HNC(1-0)/HCN(1-0) and HNC(4-3)/HCN(4-3) are good diagnostics for  $\Gamma_{\text{mech}}$  in PDRs in the following cases : (a) at gas densities less than the critical densities of the lines mentioned, and (b) in high-density PDR environments such as galaxy centres with super-solar metallicities and star-burst regions.

### HCO+

HCO<sup>+</sup> is another high density tracer. The critical densities (at 50K) of its  $J = 1 - 0$  and  $J = 4 - 3$  emission lines are  $\sim 2 \times 10^5 \text{ cm}^{-3}$  and  $\sim 10^7 \text{ cm}^{-3}$  respectively. The emission grids for both lines are shown in Figs. 12. The corresponding grids as a function of  $\alpha$  are presented in Fig. B5 in the Appendix.

**Fig. 12.** HCO<sup>+</sup>  $J = 1 - 0$  and  $J = 4 - 3$  emission in the absence of  $\Gamma_{\text{mech}}$  for solar metallicity ( $Z = Z_{\odot}$ ).

We will discuss only mid- and high-density models ( $n > 10^3 \text{ cm}^{-3}$ ), since at lower densities the lines would be too weak to be observed. With increasing  $\Gamma_{\text{mech}}$ , the emission of the  $J=1-0$  line in the high density region (and  $G_0 > 10^5$ ) decreases by a factor of  $\sim 2$ . At such high densities,  $x_{\text{HCO}^+}$  drops by three orders of magnitude, leading to the reduced emission. We trace the source of the reduced abundance of  $x_{\text{HCO}^+}$  to its slow production rate; which is reduced by an order of magnitude as  $\alpha$  increases. This slowing down is mainly due to the reaction of the ionic species HOC<sup>+</sup> and CO<sup>+</sup> with H<sub>2</sub> through which HCO<sup>+</sup> is formed. The abundance of these two ionic reactants drops by factors of two and two hundred respectively as  $\alpha$  increases, hence the slow production rate of HCO<sup>+</sup>. As long as the HCO<sup>+</sup>( $J = 1 - 0$ ) grid is concerned, the emission is enhanced everywhere else throughout the grid. See the dashed line in Figure-B5.

For PDRs with moderate densities i.e in the non-LTE phase of the rotational line of HCO<sup>+</sup>, the coupling between dust and gas is weak compared to that in high-density clouds. This weaker coupling results in a weaker dependence of the abundance on  $\Gamma_{\text{mech}}$  (since the physical conditions do not change much). However, the temperature does increase in the molecular zone where HCO<sup>+</sup> is present. This increase in the temperature enhances the emission of the  $J = 1 - 0$  line for densities  $n < 10^4 \text{ cm}^{-3}$ .

The  $J = 4 - 3$  line responds in similar way to changes in  $\Gamma_{\text{mech}}$ , but the emission decrease only for  $\alpha = 0.05$  and  $0.1$ . This emission is more sensitive to temperature changes because of the ease of populating upper levels. Thus the emission is boosted again for  $\alpha > 0.1$ , even though  $x_{\text{HCO}^+}$  decreases for  $n > 10^5 \text{ cm}^{-3}$ .

HCO<sup>+</sup> is interesting because it behaves quite differently in the mid- and high-density regimes. It can be used as a diagnostic for both regimes in combination with other species (as we discuss below).

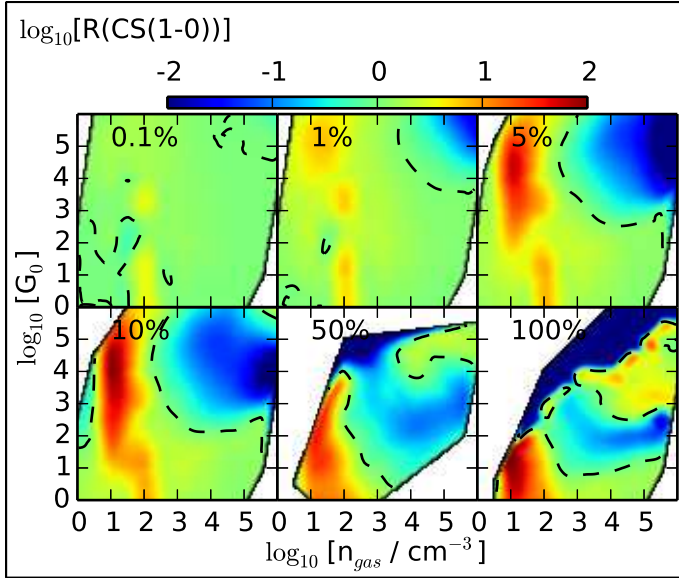

### CN

The critical densities of the CN(1<sub>1/2</sub>-0<sub>1/2</sub>) and CN(2<sub>3/2</sub>-1<sub>3/2</sub>) is in the high density part of the parameter space (see Table-3). Similar to HCO<sup>+</sup>, the emission grid of those lines also exhibits a peculiar dependence on increasing amounts of mechanical feedback. In looking at the abundance of CN, we see that at high densities  $x_{\text{CN}}$  correlates negatively with  $\alpha$ . The reduction in the abundance is caused by the high temperatures in the molecular zone of the PDR. The high temperatures leads to the destruction of CN, at a rate which is an order of magnitude higher compared to pure PDRs, through the reaction  $\text{H}_2 + \text{CN} \rightarrow \text{HCN} + \text{C}$ . The reduced abundance of CN results in the dimming emission as  $\Gamma_{\text{mech}}$  is introduced, which is evident in (Fig. -B6). Beyond  $\alpha = 0.1$   $N(\text{CN})$  becomes too low, where the intensities (in both lines considered) decrease by a factor of 10.

On the other end of the parameter space (at mid- and low densities),  $\text{N} + \text{CN} \rightarrow \text{N}_2 + \text{C}$  is the dominant reaction for the full range in  $\alpha$ . This reaction maintains a high  $x_{\text{CN}}$  in that part of the parameter space, i.e the region bounded by the dashed contour line in the bottom row (where  $\alpha = 0.1, 0.5, 1.0$ ) of the panel corresponding to CN in Figure-B6.

### CS

This species has a very distinctive dependence on  $\Gamma_{\text{mech}}$  (compared to the other molecular species we have so far considered). In Fig. 13 we see that a region of suppressed emission sweeps across the grid from high- to low- density as  $\alpha$  increases. This non-trivial behaviour is difficult to explain in detail.

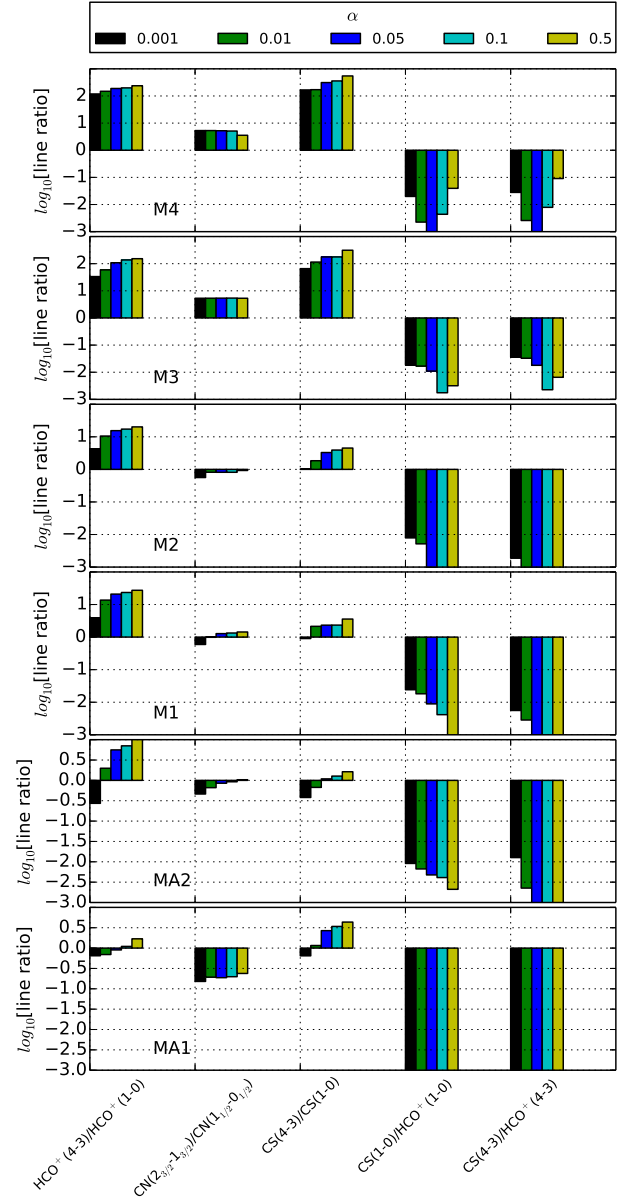

**Fig. 13.** Grids of the relative changes in the emission of the CS(1-0) line for different values of  $\alpha$  ( $Z = Z_{\odot}$ ). See also Figure-4 for a description of the colours.

The  $n_{\text{cr}}$  for CS is  $\sim 5 \times 10^4 \text{ cm}^{-3}$  and  $\sim 3 \times 10^6 \text{ cm}^{-3}$  for the  $J = 1 - 0$  and  $J = 4 - 3$  lines respectively (at 50K). Up to  $\alpha = 0.05$  both grids indicate a strong decrease in the emission

for  $n > 10^3 \text{ cm}^{-3}$  and  $G_0 > 10^3$ . The reduction in the emission is as low as a factor of 50 for high density PDRs. As  $\alpha$  increases further the emission of those PDRs starts to increase again relative to the case of  $\alpha = 0$ . This increase reaches a factor of 50 for  $J = 4 - 3$  transition. Meanwhile, the region where the emission are suppressed is pushed to lower densities and lower  $G_0$ . This is a consequence of the chemistry. At the high densities, the drop in the emission is due to reactions with cosmic rays. Those reactions become dominant in destroying CS instead of the neutral-neutral reaction  $\text{O} + \text{CS} \rightarrow \text{S} + \text{CO}$ ; which otherwise is the dominant reaction in pure PDRs.

The strong dependence of the CS lines on  $\alpha$  makes it a useful candidate for mechanical feedback.

**Fig. 14.** Line ratios of HCO<sup>+</sup>, CN and CS for  $Z = 1Z_{\odot}$  and  $A_V = 10 \text{ mag}$  for the reference models.

In Fig. 14 we show the line ratio for CS, CN, and HCO<sup>+</sup>. In all the reference models the line ratio of HCO<sup>+</sup>(4-3)/HCO<sup>+</sup>(1-

0) and particularly the interspecies CS/HCO<sup>+</sup> ratios vary over more than one order of magnitude as a function of  $\alpha$ . The CS(4-3)/CS(1-0) ratio shows some dependence on  $\Gamma_{\text{mech}}$ , but again those variations are small compared to the ones mentioned before. The line ratios CS(1-0)/HCO<sup>+</sup>(1-0) and CS(4-3)/HCO<sup>+</sup>(4-3) are more interesting. In looking at the CS grids in Figs. 13, we see that variations are well described in the CS/HCO<sup>+</sup> ratios, which allows them to be used diagnostically to constrain  $\Gamma_{\text{mech}}$  in extreme star-bursts. For instance a ratio less than 0.01 would imply an  $\alpha \sim 0.05$ ; whereas a ratio around 0.1 implies  $\alpha > 0.1$  (see last column in Fig. 14).

In M1 and M2, the line ratio behaviour is the same at higher or lower metallicities (see Fig. B7). In M3 and M4, this ratio's response to changes in  $\alpha$  is slightly weaker at  $Z = 0.5 Z_{\odot}$ . In the lowest metallicity case, CN(2<sub>3/2</sub>-1<sub>3/2</sub>)/CN(1<sub>1/2</sub>-0<sub>1/2</sub>) decreases to unity as  $\alpha$  increases. This might be useful in probing  $\Gamma_{\text{mech}}$  in e.g. dwarf galaxies.

### 3.4. Other line ratios

Fig. 15 shows some other molecular line ratios, selected to illustrate their importance as a diagnostic for  $\Gamma_{\text{mech}}$  in PDRs.

Most of the line ratios exhibit an order of magnitude change for  $\alpha \lesssim 0.25$ . Typical examples are HCO<sup>+</sup>(1-0)/CO(1-0) and HCN(1-0)/CO(1-0) in the high-density models such as M3 and M4. On the other hand, HCO<sup>+</sup>(1-0)/<sup>13</sup>CO(1-0) shows an irregular increase as a function of  $\alpha$  in these models, but a strictly monotonous increase (from  $\sim 0.01$  to 1) is observed in the lower density models M1 and M2.

Ratios involving lines of HCN with CO and HCO<sup>+</sup> are excellent candidates for constraining  $\Gamma_{\text{mech}}$ . This is also the case at lower and higher metallicities (see Fig. B8) for all the representative models. In some cases, such as HCN(4-3)/HCO<sup>+</sup>(4-3) in M4, the ratio increase from  $\sim 0.3$  to 10 for  $\alpha \sim 0.1$ . One drawback in the HCN(1-0)/CO(1-0) ratio is the degeneracy in its dependence on  $\Gamma_{\text{mech}}$  in M3. For example in the absence of  $\Gamma_{\text{mech}}$ , this ratio has a value of 0.3. It reaches a minimum of 0.01 (for  $\alpha = 0.1$ ) and increases back to  $\sim 0.3$  for extreme cases where  $\alpha = 0.5$ . Cases of such degeneracies can be resolved by simultaneously considering other line ratios, as we will demonstrate at the end of this section.

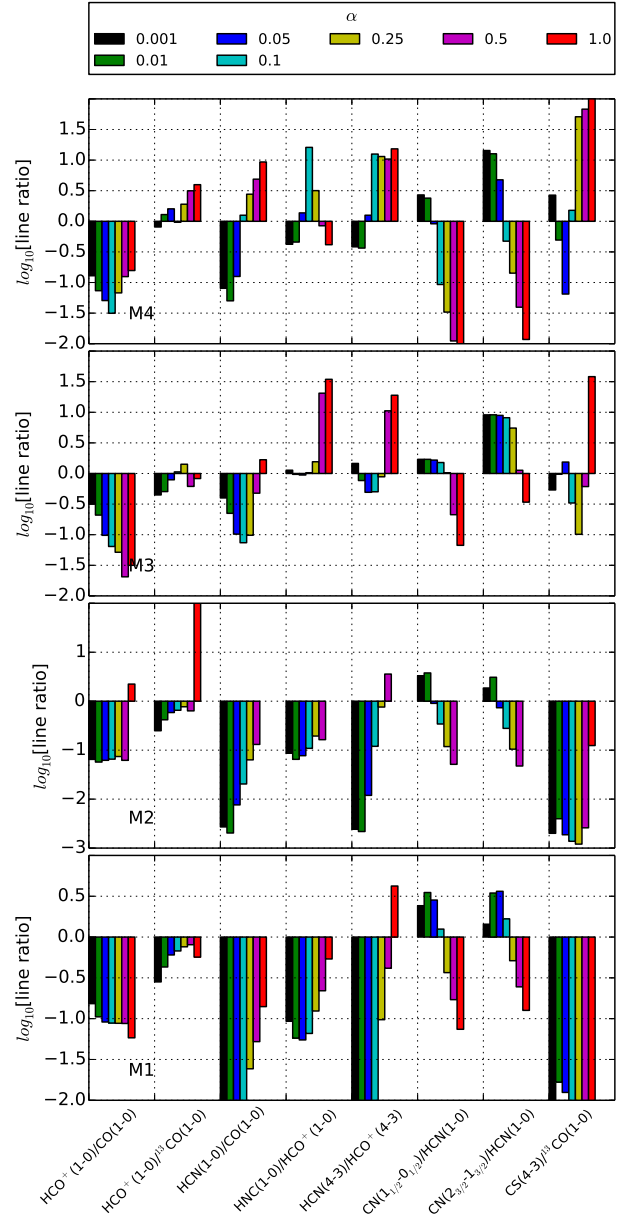

We draw special attention to the CN/HCN interspecies ratios. They have a very strong dependence on  $\Gamma_{\text{mech}}$ , showing a decrease by an order magnitude for the lowest transition ratios as  $\alpha$  increases from 0 to 1.

In summary, we found that line ratios between CN, HCN and HCO<sup>+</sup> are quite useful in constraining  $\Gamma_{\text{mech}}$ . This is true in particular for CN since  $\Gamma_{\text{mech}}$  seems to drive ratios to values well below unity for most clouds when  $\alpha > 0.1$ . In high-density clouds whose heating budget is dominated by  $\Gamma_{\text{mech}}$ , line ratios of HNC/HCO<sup>+</sup> tend to exceed unity.

## 4. Application

We have presented model predictions for line intensities and line ratios of many molecular species. However, we have not yet reflected on any observational data to which these models can be applied. In this section we use actual data and demonstrate a) the importance of molecular line ratios as a diagnostic for mechanical heating and b) their usefulness as a tool for constraining it.

In Table-4, we present the range of line ratios involving HCN, HNC, CO and HCO<sup>+</sup> for infra-red luminous galaxies taken from Table-B.2 in Baan *et al.* (2008).

**Fig. 15.** Line ratios with strong dependence on  $\Gamma_{\text{mech}}$  for  $Z = 1Z_{\odot}$  for the reference models.

We follow a simplistic approach to an ambitious goal. Our aim is to constrain  $(n, G_0, A_V, \alpha)$  using the data at our disposal. The only major assumption we make is the metallicity of the source. Here we will assume solar metallicity.

In Figure-16 we present a step-by-step procedure to constrain  $(n, G_0, A_V, \alpha)$  using line ratio grids parametrized with those four quantities. Each small square represents a grid as a function of  $n$  (horizontal axis) and  $G_0$  (vertical axis), like all the previous grids that we have shown so far. Each collection of grids illustrates the constraining procedure for a certain  $A_V$ . The collection of grids in Figure-16 corresponds to  $A_V = 5$  mag. The ones for  $A_V = 10$  and 30 mag can be found in the appendix in Figures-C7 and C8. In each column, grids for different  $\alpha$  are presented.

In the top row of each collection, regions where the line ratio of HCN(1-0)/HNC(1-0) is within the observed range (see Table-4), are delineated in light blue. Clearly, the HCN(1-0)/HNC(1-0)

ratio	range	reference
HCN(1-0)/HNC(1-0)	1.5 – 4.0	<sup>a</sup>
HCN(1-0)/HCO <sup>+</sup> (1-0)	0.6 – 3.2	<sup>a</sup>
HNC(1-0)/HCO <sup>+</sup> (1-0)	0.3 – 1.0	<sup>a</sup>
HCO <sup>+</sup> (4-3)/CO(1-0)	0.1 – 0.5	<sup>b,c</sup>

**Notes.**<sup>(a)</sup> From Baan *et al.* (2008)<sup>(b)</sup> From Israel *et al.* (1995)<sup>(c)</sup> From Knudsen *et al.* (2007)**Table 4.** Observed ranges of molecular line ratios for some starburst galaxies.

ratio does not constrain all four parameters. However if  $A_V$  and  $\alpha$  are known, one can constrain the range in  $n$  and  $G_0$  for the source. For example, if we know a priori that  $A_V = 5$  mag and  $\alpha = 0$  (pure PDR), then the UV flux is constrained to  $G_0 > 10^5$  (see the grid with  $\alpha = 0$  in the first row of Figures-16) while the gas density is not constrained. On the other hand, if  $\alpha$  is known to be 0.5 (which is quite extreme), then  $n$  and  $G_0$  are constrained to a much narrower region. Including the information about HCN(1-0)/HCO<sup>+</sup>(1-0) from Table-4, helps us better constrain all four parameters (see the second row in the mentioned Figures). Although now  $n$  and  $G_0$  are better constrained (cyan regions),  $\alpha$  is still degenerate. Similarly, HNC(1-0)/HCO<sup>+</sup>(1-0) fails in achieving our goal [yellow zones in the third row].

Based on our observation in the results section, that  $\Gamma_{\text{mech}}$  has a strong signature on high- $J$  transitions (which was more or less ubiquitous for all species), we attempt adding ratios of observed lines involving a high- $J$  and a low- $J$  transition. We use the  $J = 4 - 3$  transition of HCO<sup>+</sup> of NGC253 as a guide. It is clear that this ratio manages to constrain all four parameters, with moderate certainty to,  $A_V \sim 5$  mag,  $10^{3.5} < n < 10^4$ ,  $10^4 < G_0 < 10^{4.5}$  and  $\alpha \sim 0.1$ . This may not be a unique find; however, we expect the  $\chi^2$  value (or the minimum for a proper statistical fit) to be close to the range constrained by this proof of concept simple demonstration.

**5. Conclusion and discussion**

We have studied the effect of  $\Gamma_{\text{mech}}$  on a wide range of parameter space in  $n$  and  $G_0$  covering six order of magnitude in both ( $1 < n < 10^6 \text{ cm}^{-3}$  and  $1 < G_0 < 10^6$ ). Throughout this parameter space we investigated the the most important and commonly observed molecular emission and atomic fine-structure lines and their ratios. The explored range in mechanical heating ( $\Gamma_{\text{mech}}$ ) covers quiescent regions, with almost no star-formation, as well as violently turbulent star-bursts. The star-formation rates for those range from  $0.001 \text{ M}_\odot \text{ yr}^{-1}$  to  $\sim 100 \text{ M}_\odot \text{ yr}^{-1}$  respectively.

The two fundamental questions we try to answer in this paper are: (a) is it possible to constrain the mechanical heating rate in a star-forming region by using molecular line ratios as a diagnostic? (b) how important is  $\Gamma_{\text{mech}}$  in recovering the molecular H<sub>2</sub> mass of a star-forming region using observed molecular line emission such as those of CO?

Before discussing these questions, we state the main characteristics of mechanically heated PDRs we observed in our grids:

- The most significant contribution of  $\Gamma_{\text{mech}}$  to the atomic fine-structure line intensities results from enhanced temperatures in the molecular zone. This is especially the case for

the [CI] lines. For clouds whose density is below the critical density of those lines, half of the emission intensity emanates from the molecular zone. FS line ratios, such as [CII]  $158\mu\text{m}/[\text{CI}]$   $369\mu\text{m}$ , [OI]  $63\mu\text{m}/[\text{CI}]$   $369\mu\text{m}$  and [CI]  $369\mu\text{m}/[\text{CII}]$   $609\mu\text{m}$ , are good diagnostics for  $\Gamma_{\text{mech}}$  in low-density PDRs ( $n < 10^3 \text{ cm}^{-3}$ ).

- High- $J$  to low- $J$  transitional ratios of <sup>12</sup>CO and <sup>13</sup>CO, such as CO(16-15)/CO(1-0), are good diagnostics for  $\Gamma_{\text{mech}}$  over the whole density range considered. In contrast low- $J$  CO line ratios, such as CO(2-1)/CO(1-0) or CO(4-3)/CO(1-0), are useful as diagnostics<sup>3</sup> only for clouds with  $n < 10^3 \text{ cm}^{-3}$ .
- The line ratios of <sup>13</sup>CO/<sup>12</sup>CO (in both low- $J$  and high- $J$  transitions) have a strong dependence on  $\Gamma_{\text{mech}}$ . They decrease as  $\Gamma_{\text{mech}}$  increases. This complements the range in density where low- $J$  transitions of <sup>12</sup>CO (and <sup>13</sup>CO) can be used as diagnostics for  $\Gamma_{\text{mech}}$ .
- At high metallicities ( $Z = 2 Z_\odot$ ), HCN and HNC are very good diagnostics for  $\Gamma_{\text{mech}}$  when  $G_0 \gtrsim 10^5$ , such sources include star-bursts in galaxy centres.
- Line ratios such as HCN(1-0)/CO(1-0), HCN(1-0)/HCO<sup>+</sup>(1-0), CN(1<sub>1/2</sub>-0<sub>1/2</sub>)/HCN(1-0), CN(2<sub>3/2</sub>-1<sub>3/2</sub>)/HCN(1-0), CS(1-0)/HCO<sup>+</sup>(1-0) show a strong dependence of  $\Gamma_{\text{mech}}$ , hence they are a good diagnostic of it.

The major conclusions of the paper, which we demonstrated in the application section is: low- $J$  transitions alone are not good enough to constrain mechanical heating; ratios involving high- $J$  to low- $J$  transitions do a much better at that.

Another major conclusion is the importance of  $\Gamma_{\text{mech}}$  in constraining  $A_V$  or, equivalently, the hydrogen column density  $N_{\text{H}}$ , which can be used to determine the molecular mass of the cloud. In comparing Figure-16 to the ones of higher  $A_V$  in the appendix, one can see that if  $\Gamma_{\text{mech}}$  is ignored, it is easy to under- or over-estimate the  $A_V$  by a factor of five (or more). Ignoring  $\Gamma_{\text{mech}}$  also results in more than an order of magnitude error in estimating the  $n$  and  $G_0$ . For instance in looking at the last row of Figure-16, one can see that when  $\Gamma_{\text{mech}}$  is ignored, an error up to two orders of magnitude can be done in constraining the ranges of  $n$  and  $G_0$ .

We emphasize that our approach in constraining the physical parameters of clouds using the observed line ratios, is just a proof of concept demonstration. Ultimately one must use more elaborate minimization methods to attempt to constrain the physical parameters. However, it is most likely that the parameters which best fit the observations, will be very close to the ones obtained using the method adopted in the application section. We leave it to the interested reader to make use of the grids which are published as well with this paper (see Figures-C5, C4, C3 in the appendix).

We finalize our discussion by touching on the effect of cosmic rays (CR). Although it is outside the scope of this paper, we explored the effect of enhanced CR rates. Diagnostic line ratio grids for HCN, HNC and HCO<sup>+</sup> are fundamentally different from those which are dominated by  $\Gamma_{\text{mech}}$  (see Figure-C6). Hence, we expect that in using diagnostics presented in this paper, clouds which are embedded in environments where the CR rate is enhanced, would not be mistaken with clouds whose heating budget is dominated by  $\Gamma_{\text{mech}}$ .

*Acknowledgements.* MVK would like to thank Marissa Rosenberg for useful insight on the observations and some aspects of the of the modelling and the fitting

<sup>3</sup> We refer the reader to the end of this section for a small discussion on the difference about regions dominated by cosmic-rays in comparison to ones dominated by  $\Gamma_{\text{mech}}$ .

**Fig. 16.** Constraining the  $\Gamma_{\text{mech}}$ ,  $A_V$ ,  $n$  and  $G_0$  for starburst galaxies. In this figure we illustrate the procedure used to constrain those parameters for  $A_V = 5$  mag, the figures for the remaining  $A_V$  are in Figures-C7, C8. Each row corresponds to a certain line ratio, and each column corresponds to a certain  $\alpha$ . The colors correspond to regions where the observed line ratio in each grid is within the observed range of Table-4. In the first row regions where HCN(1-0)/HNC(1-0) is between 1.5 and 4.0 is shaded in light blue. In the second row we include HCN(1-0)/HCO<sup>+</sup>(1-0). The regions which are within the observed line ratios for both HCN(1-0)/HCO<sup>+</sup>(1-0) and HCN(1-0)/HNC(1-0) are shaded in cyan. In the third row, we introduce HNC(1-0)/HCO<sup>+</sup>(1-0), the region satisfying all three line ratios is shaded in green. We notice that green regions exist for all values of  $\alpha$  in the third row. Hence we can not constrain  $\alpha$  so far. It is only when HCO<sup>+</sup>(4-3)/CO(1-0) is included,  $\alpha$  is constrained to 0.1 (red region in the  $\alpha = 0.1$  column) in the last row. Although much smaller red regions are also visible for  $\alpha = 0.05$  and  $\alpha = 0.25$ , the global minimum would be most likely around  $\alpha = 0.1$  region. In applying a similar procedure to grids corresponding to  $A_V = 10$  and 30 mag, we do not observe any red region.

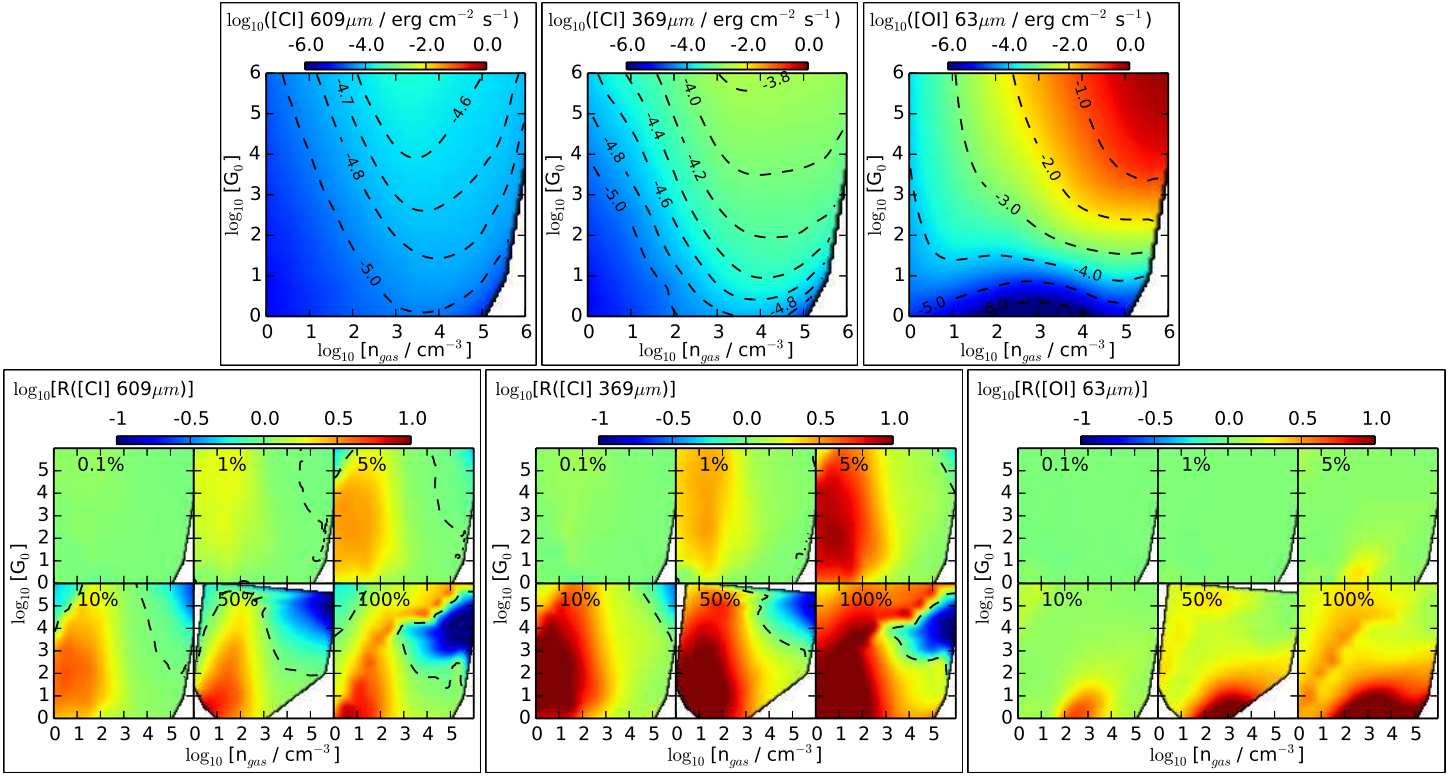

procedures. The author is grateful also to Alessandra Candian, who provided some guidance on molecular properties. The author would also like to thank F. S. van der Tak for some information on RADEX. Finally, MVK would like to thank the anonymous referee whose comments and suggestions helped improve the paper significantly.
